MODULATION, R-F AND I-F AMPLIFICATION, DETECTION

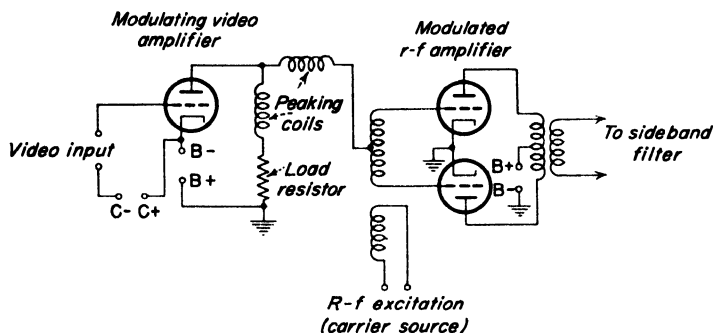
48. Video Modulation. Video modulation is based on the same considerations as audio modulation, with certain specialized requirements. One of the limitations is the small amount of video-signal voltage which may be generated in currently available tubes and circuits. The high capacitance to ground of large water-cooled tubes requires the use of very low values of load resistance to maintain response over the v-f range. The voltage which can be developed across the load resistance depends on the emission current. At present it is difficult to generate more than the 1,500 or 2,000 volts peak to peak over the video range from 30 cps to 4.5 Mc. When high-level modulation is used, therefore, it is usually considered expedient to use grid-circuit modulation, rather than plate-circuit modulation, since the voltage requirements for grid modulation are less by the amplification factor of the modulated stage. Low-level modulation is not similarly restricted but requires a number of linear class B r-f amplifier stages following the modulator.


Fig. 40. Fundamental circuit of video modulator.

The second unusual requirement in video modulation is the necessity for maintaining two levels in the modulation envelope at constant amplitudes. These levels are (1) the tips of the sync pulses, *i.e.*, the maximum amplitude of the envelope, and (2) the blanking level or pedestal. Since these levels must remain constant regardless of any changes in the wave form of the camera-signal component, it is necessary to couple the modulating amplifier conductively to the modulated amplifier. This makes necessary a separate power supply for each stage. A typical arrangement is shown in Fig. 40. Here the modulating video amplifier is coupled conductively to the grids of the r-f amplifier. The B supply for the modulating amplifier is in series with the cathode.

At the grid of the modulating amplifier, it is necessary that the blanking level and sync-pulse tip level be constant. The latter levels are caused to assume fixed values by passing the video wave form through a diode rectifier whose cathode is connected to the modulating video-amplifier grid. The load circuit values are chosen so that the rectified d-c potential across the diode assumes a level at the tips of the sync pulses, or just below the tips (the difference being required to supply the diode current). The voltage across the diode forms a part of the fixed bias of the modulating amplifier. The composite wave form, extending more positively than the tips of the sync pulses, causes the modulating amplifier output voltage to extend more negatively than the sync pulses. This output voltage, applied to control the amplitude of the modulated r-f amplifier, causes the sync-pulse tips to assume the peak position in the envelope, while the blanking level and camera-signal components extend to lower levels in the envelope. The sync pulses and blanking level maintain constant amplitudes, whereas the average on the camera-signal component changes with the background illumination of the scene (see Fig. 10).

49. Vestigial-side-band Transmission. The side bands of the modulated r-f signal, assuming a maximum video modulating frequency of 4.5 Mc, extend over a total region of 9 Mc. To conserve space in the ether and at the same time to secure greater efficiency from r-f and i-f amplifiers, the FCC standards specify vestigial-side-band transmission ("single"-side-band transmission). In this system a part of the lower-frequency side band is completely attenuated. By this means the upper side band can be transmitted completely with 4.0 to 4.5 Mc width within the 6-Mc channel assigned by the FCC. A portion of the lower side band, within 1.25 Mc of the carrier frequency, is also transmitted.

The channel composition for vestigial-side-band transmission is shown in Fig. 41, at the top. The lower figure shows the corresponding characteristic of the receiver. In the receiver characteristic the picture signal-carrier voltage is attenuated to 50 per cent of its original level, and the curve of attenuation is linear over a range of 2.5 Mc. This arrangement develops 50 per cent modulation in those portions of the carrier which receive double-side-band treatment (within 1.25 Mc of the carrier). The components further removed from the carrier in the upper side band are inherently 50 percent modulated, so all portions of the signal, when presented to the detector, produce an equal amplitude in the detector output.

FIG. 41. (*Top*) Output characteristic of television transmitter. (*Bottom*) Corresponding response characteristic of receiver.

To form a transmitted signal of the character shown at the top in Fig. 41, a filter having sharp cutoff characteristics is required. The desired upper side band is passed through a capacitor to the antenna, whereas the undesired lower side band is passed through an inductance to an absorbing resistor. Filter structures for this purpose, when employed for high-level modulation, are customarily formed from sections of coaxial transmission lines. In addition to the filter shown, a sharply tuned "notching filter" is usually used to provide additional attenuation at the sound-carrier frequency of the adjacent channel. The characteristic shown in Fig. 41 may also be obtained with low-level modulation by proper positioning of the pass bands of the linear class B stages that follow the modulator.

SEPARATION OF THE SYNCHRONIZING SIGNALS

50. Amplitude Separation. The separation of the composite synchronizing signal from the camera signal is performed after the composite video signal has been developed by the second detector. The composite video signal (Fig. 42*B*) is applied to a "clipper" tube. In Fig. 43 a diode clipper is shown in conjunction with the second detector. It is necessary that the clipping level be maintained continuously at the blanking level to ensure that the camera signal does not affect synchronization and that the maximum amplitude of sync pulses is developed.

51. Wave-form Separation. After the composite synchronizing signal has been separated from the video signal, it is necessary to develop the horizontal sync pulses independently of the vertical sync pulses. The latter separation is carried out by wave-form separation, since the two sets of pulses cannot be distinguished by ampli-

tude means. Essentially wave-form separation depends on circuits which respond to the relative frequency content of the two sets of pulses. The horizontal sync pulses that are of short duration occur 15,750 times per sec and have a predominance of h-f components, whereas the vertical pulses that are of long duration and occur 60 times per sec have a predominance of l-f components. The ratio of the frequencies
FIG. 42. (*A*) Demodulation of the modulated picture carrier by a diode detector, showing clipping level which separates the camera signal from the synchronizing pulses. (*B*) Clipper circuit and characteristic, used to separate sync signals from camera signals.

of the two sets of pulses 15,750/60 = 262½ is the index of the degree of frequency difference on which the separator circuits may operate.

52. Differentiator Circuit for Horizontal Sync Pulses. The differentiator of Fig. 44 develops the h-f components of the composite synchronizing signal, *i.e.*, the horizontal sync pulses. The series capacitance passes the high frequencies associated with the leading edge of the sync pulse, while retarding all lower-frequency components. The *RC* product (time constant) of the combination is made short compared with the frame-
FIG. 43. Combined second detector and sync amplitude separator (clipper).
FIG. 44. Differentiator for horizontal sync pulses.

repetition interval (1/60 sec) and long compared with the line scanning interval (1/15,750 sec). The leading edge of the differentiated wave forms is applied, in the proper polarity, to the synchronizing terminal of the horizontal scanning generator.

53. Integrator Circuit for Vertical Sync Pulses. The integrator circuit of Fig. 45 develops a sync pulse from the serrated vertical pulse and equalizing pulses. The

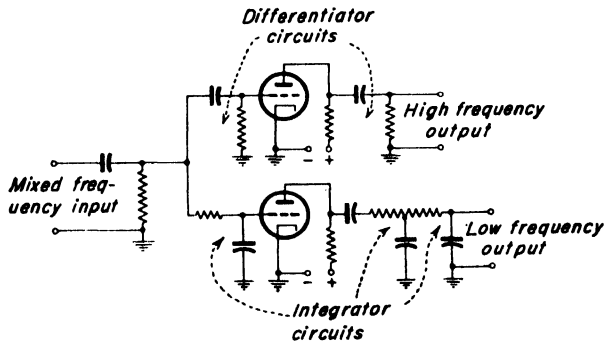
wave forms of input and output are shown. Note that the initial portion of the integrated output pulse is not so sharply rising as that of the differentiated horizontal pulse, and consequently the intersection with the synchronizing control level is not so precisely marked. This makes it necessary to have the wave shape of each successive
FIG. 45. Integrator circuit and action on vertical sync pulses.


FIG. 46. Combined differentiator and integrator circuits for wave-form separation.

integrated pulse precisely the same. The function of the equalizing in this respect has been pointed out. In addition it is necessary that all traces of the horizontal sync pulses be completely removed from the integrating circuit.

Several differentiating and integrating circuits may be used in cascade to improve the degree of separation. The cascaded circuits may be connected directly together (usually done with integrator circuits), or they may occur in the grid and plate circuits of a sync separator tube as in Fig. 46.

PICTURE TUBES AND ASSOCIATED CIRCUITS

54. Picture Tubes. The conventional picture tube is a funnel-shaped evacuated structure containing an electron gun which forms an electron beam, and a fluorescent screen on which the beam impinges. The beam is deflected by the application of transverse electric or magnetic fields which cause the end of the beam to trace out the interlaced scanning pattern over the fluorescent screen. The current in the beam is capable of variation from zero (cutoff) to a maximum of several hundred microamperes, under the control of the signal potential applied between the cathode and the control electrode of the electron gun.
Fig. 47. Structure of typical picture tube.

The beam is deflected synchronously with the scanning agent in the camera tube, and the beam current is controlled by the camera signal. Variations in the beam current produce corresponding variations in the brightness of the fluorescent spot, and the picture is thereby reproduced.

The characteristics of picture tubes depend on the design of the electron gun and on the physical and chemical properties of the fluorescent screen. The electron gun requires a power supply to form the beam. Finally the deflection fields must be provided by scanning generators, and these generators must operate under the control of the synchronizing signals of the video signal.

Picture tubes are classified according to (1) the type of focusing employed (electrostatic or magnetostatic) in the electron gun, (2) the type of deflection (electric or magnetic), (3) the type of phosphor (sulfide and nonsulfide), and (4) the color of the light produced (usually white).

55. Characteristics of Electron Guns. Electrostatically focused electron guns are characterized (1) by the ratio of the voltages applied to the second anode and the first anode. In present designs this ratio varies from 4 to 6. In addition the guns are characterized (2) by the control electrode characteristic which specifies the relation between control electrode voltage and beam current (second-anode current) for different values of second-anode voltage. A typical control characteristic of an electrostatically focused gun employed in the 12AP4 tube is shown in Fig. 48. Curves of this shape are typical of all types of electron guns, whether electrostatically or magnetostatically focused.

Fig. 48. Electron-gun control characteristic; (*A*) 7,000-volt, (*B*) 6,000-volt second-anode voltage.

An important characteristic is the degree of fineness of focus, *i.e.*, the size of the fluorescent spot formed on the screen. Guns of good design are capable of forming a spot about 0.005 in. in diameter, but production tubes usually have spots from 0.01

to 0.015 in. in diameter. The latter spot size permits a picture resolution of 350 lines when the picture height is 6 in. or more (picture width 8 in. or more).

56. Characteristics of Phosphors. The important characteristic of the phosphors (fluorescent materials) employed in picture tubes is the relationship between the
FIG. 49. Type P4 phosphor light-output characteristic.

light produced, the beam current (second-anode current), and the second-anode potential. Figure 49 shows a typical family of such curves, taken for the "P4" white-light phosphor. A recent improvement is the aluminum-backed phosphor, which has superior brightness and contrast when operated at voltages of 9,000 volts or higher.

57. Transfer Characteristic of Picture Tube. The transfer characteristic of a transducer in a television system is the relationship between the significant variational input quantity and the significant variational output quantity. In picture tubes the significant input is the control-electrode voltage, and the significant output is the corresponding light produced on the screen. The transfer characteristic of the 12AP4 tube is shown in Fig. 50. Note that the relationship is not linear but has the "antisaturation" shape. This characteristic tends to enhance the apparent contrast of the picture.

FIG. 50. Typical transfer characteristic of a picture tube, derived from Figs. 48 and 49.

58. Contrast in Picture Tubes. The ratio of the brightness of the brightest portion of an image to the brightness of the darkest portion is called the *brightness-contrast range*. Owing to the effects of light spreading (halation) within the glass envelope the maximum contrast ratio of current tubes is about 100:1. Between closely adjacent portions of the image, halation reduces the maximum obtainable contrast to about 30:1.

59. Dynamic Action of Picture-tube Control Circuit. The dynamic action of the picture-tube circuit is represented by applying the video signal wave form to the transfer characteristic (Fig. 51). The video wave form is applied so that the blanking level corresponds to the zero light (cutoff) point on the transfer characteristic as shown. This bias level must remain fixed. Then the camera signal extending to the right of the blanking level produces light on the screen in accordance with the camera signal, whereas the synchronizing signals to the left of the blanking level are in the infrablack region (beyond cutoff) and do not produce light. The total excursion of the camera signal should be limited so that the control-electrode voltage never becomes positive; usually the control electrode does not go beyond the −5 or −10 volts mark. The average of the picture signal component, taken over the frame interval, establishes the background brightness of the scene, provided the blanking level remains fixed at the light cutoff point.

Fig. 51. Dynamic action of video signal in picture-tube control circuit.

60. D-c Restoration Circuits. Typical circuits used to maintain the blanking level constant at the picture-tube control electrode are shown in Fig. 52. The proportions of C_c and R_g are chosen to have a time constant long compared with the line-scanning interval but short compared with the duration of the changes in background light. In the upper diagram the grid and cathode of the v-f tube act as a diode, whereas in the lower case a separate diode is employed. The diode, acting in conjunction with C_cR_g, develops a bias equal to the peak of the video signal. This peak value remains fixed (assuming no change in signal strength); consequently the remainder of the video signal (the camera-signal components) acts in series with a fixed bias. This fixed bias is coupled conductively (either through the amplifier tube, at the top, or directly, at the bottom) and forms a part of the control-electrode bias. By this means the blanking level remains fixed, and, if the total
Fig. 52. D-c restoration circuits. (*Top*) Using the video amplifier grid current for rectification. (*Bottom*) Using a separate diode for rectification.

control-electrode bias is fixed so that the blanking level coincides with the light cutoff point, the background brightness of the scene depends only on the average of the camera-signal component, as is required.

61. Picture-tube Power Supplies. The picture-tube power supply consists of (1) a source of high voltage for the first and second anodes, which draw the electrons from the gun and (in the case of electrostatically focused tubes) bring the beam to focus, (2) a source of heater current for the cathode, and (3) a source of focusing coil current (in the case of magnetostatically focused tubes).

A typical high-voltage power supply is shown in Fig. 53. It consists of a single-winding transformer of rms output voltage equal to approximately $V_{dc}/1.4$, where V_{dc} is the desired output d-c voltage; two capacitors of roughly 0.03 to 0.05 μf; a series filter resistor of roughly 100,000 to 500,000 ohms; and a tapped bleeder resistor of about 5 megohms. A resistor in series with the second-anode output tap limits the total output current to a safe
Fig. 53. Typical anode voltage supply for picture tube.

value in case of accidental contact by the operator. The taps required for the various electrodes of an electrostatically focused electron gun are shown.

The current required for the focusing coil of a magnetostatically focused gun depends on the focus-coil design. A typical value is 100 ma at 25 volts, which may be obtained from the receiver proper at the sacrifice of 25 volts in the low-voltage power supply for the receiver.

Heater currents are usually 2.5 volts at 2.1 amp, or 6.3 volts at 0.6 amp.

The high-voltage a-c power may also be derived from (1) high-voltage pulses appearing across the horizontal scanning transformer primary or (2) an h-f oscillator. In the latter case the filtering is simplified, since small values of filter capacitance suffice.

DEFLECTION OF ELECTRON BEAMS

62. Electron-beam Velocity. The amount of deflection suffered by an electron scanning beam depends on the velocity with which the electrons in the beam move. This velocity v is expressed by

$$v = 3 \times 10^{10} \sqrt{1 - \left(\frac{1}{2 \times 10^{-6}E + 1}\right)^2} \quad \text{cm per sec} \qquad (30)$$

where E is the accelerating voltage in volts (approximately equal to the second-anode voltage). This expression takes into account the change in electron mass with velocity. Values of v vary from 2.66×10^9 cm per sec at 2,000 volts to 9.86×10^9 cm per sec at 30,000 volts.

63. Electric Deflection. The deflection d of the scanning beam across the screen of a picture tube caused by passage between parallel deflecting plates is given by

$$d = \frac{1.77 \times 10^{15} E_d l (D + \frac{1}{2}l)}{sv^2} \quad \text{cm} \qquad (31)$$

where E_d = voltage applied to deflection plates, volts
v = electron beam velocity, cm per sec
l = length of deflection plates, cm
s = separation between them, cm
D = distance from screen end of deflection plates to center of screen measured along axis of tube, cm

Typical electrically deflected tubes have deflection sensitivities of from 0.15 to 0.35 mm deflection per volt applied to the deflecting plates, when operated at maximum rated second-anode voltage.

64. Magnetic Deflection. The deflection d across the screen of a picture tube, caused by passage through a uniform magnetic field, is given by

$$d = \frac{1.77 \times 10^7 BlD}{v} \quad \text{cm} \tag{32}$$

where B = flux density of field, gausses
l = its length, cm
D = field-to-screen distance, cm
v = electron-beam velocity, cm per sec

65. Ion Spot. Negative ions liberated from the cathode of the electron gun are focused and deflected in much the same manner as the electrons. In electric deflection the deflection is independent of the charge/mass ratio of the particles; hence the ions and electrons are equally deflected. In magnetic deflection, however, the deflection depends on the square root of the charge/mass ratio. Since the ions have masses several thousand times that of the electron, they suffer correspondingly small deflection. The lack of deflection subjects the center of the scanned area to continual bombardment by the ions, and this eventually results in the formation of a black or yellowish spot. The ion spot is characteristic of the combination of electrostatic focusing and magnetic deflection. Specialized electrode structures have been devised, however, which intercept the ions before they reach the screen. The aluminum-backed phosphor (Sec. 56) is free from ion spot since the aluminum inhibits ionic bombardment.

SCANNING AND SYNCHRONIZATION

66. Saw-tooth Generators. The saw-tooth wave form (Fig. 7) is generated for scanning purposes by the periodic charging and discharging of a capacitor. The charge-time curve is used to produce the active scanning motion, and the discharge curve forms the retrace. To maintain a linear charge curve, it is customary to restrict the charge time to about 0.4 times the RC product of the circuit, or less, and also to make use of the nonlinear dynamic characteristic of the following amplifier to introduce a compensating nonlinearity. Certain forms of multivibrator circuits may be used to produce saw-tooth waves directly.
Fig. 54. Blocking-oscillator type of impulse generator.

Usually a separate *discharge tube* is used to discharge the capacitor. The discharge current is passed through a high-vacuum triode whose grid controls the timing of the discharge. The impulses applied to the grid of the discharge tube are usually derived from an impulse generator, although they may consist of the synchronizing signal itself, properly amplified.

Impulse generators used to control the discharge tube in scanning generators take one of two forms, the multivibrator or the blocking oscillator. The blocking oscillator (Fig. 54) consists of a grid-plate-coupled oscillator whose grid is driven negative by the passage of grid current, thus blocking the oscillations suddenly. As the charge leaks off the grid through the grid resistor, the oscillations recommence, to be followed by the sudden blocking of the grid circuit. The sharp impulses appearing between grid and ground are used to control the discharge tube as shown.

Fig. 55. Multivibrator type of impulse generator.

A multivibrator type of saw-tooth generator is shown in Fig. 55. This circuit oper-

ates by virtue of the connection between the plate circuit of the output tube and the grid circuit of the input tube. The alternate charge and discharge of the coupling capacitor can be used to produce either impulses or saw-tooth waves, depending on the circuit constants.

67. Production of Current Saw-tooth Waves. Saw-tooth waves of voltage produced by saw-tooth generators suffice to deflect the beam of an electrically deflected tube, which is a voltage-operated device, provided only that the peak-to-peak value of the saw-tooth wave is great enough to produce full deflection. In magnetically deflected tubes the deflection is proportional to the current in the deflection coils; hence saw-tooth waves of current are required. The voltage wave form required to produce saw-tooth waves of current depends on the inductance and resistance present
FIG. 56. Saw-tooth waves of current and corresponding voltage wave forms in circuits of *R*, *L*, and *LR*.

in the scanning-coil windings. An "impulse" voltage wave is required for coils exhibiting a large inductance-resistance ratio. For lower L/R ratios the voltage wave form is a combination of impulse and saw-tooth waves. The several voltage and current wave forms for these cases are shown in Fig. 56.

The part-impulse part-saw-tooth wave form may be produced simply by applying a saw-tooth wave to a series *RC* combination. The saw-tooth component develops across the resistance, while the impulse portion develops across the capacitance.

The presence of distributed capacitance in the scanning-coil windings gives rise to resonance oscillations when the impulse voltage wave form is applied. These residual oscillations may be damped out by connecting a rectifier tube and a shunt *RC* circuit in series across the scanning-coil terminals.

68. Amplification of Scanning Wave Forms. The preservation of the scanning wave form in the amplifier subsequent to the scanning generator is based on the considerations for video amplifiers. Usually it is desirable to pass the fundamental and 20 harmonics, which makes the range 60 to 1,200 cps for the vertical scanning amplifier and 15,750 to 315,000 cps for the horizontal amplifier. The phase and amplitude characteristics must be linear over these ranges.

For electric deflection it is essential that the scanning-generator output be disposed symmetrically with respect to the deflection plates, and this is carried out by push-pull amplification. The center point of the push-pull output is connected through a high resistance to the second-anode terminal of the picture tube. Care must be taken to allow the necessary peak-to-peak voltage to develop across the amplifier output without breakdown of insulation and excessive stress in the tube structures. The necessity for high scanning voltages has limited application of electric deflection to tubes operating below 6,000 volts, second-anode voltage.

In magnetic deflection, heavy current rather than high voltage is required to secure full deflection. To secure the current, it is customary to employ a voltage step-down

transformer in the output of the scanning amplifier. This transformer must meet the amplitude- and phase-frequency characteristics of the amplifier itself. High voltage develops across the primary of this transformer as a result of the rapid changes of current in the secondary. The amplifier tubes and other components must be capable of withstanding these voltage peaks, which often attain several thousand volts amplitude.
Fig. 57. Construction of typical scanning yoke (magnetic-deflection coil system).

69. Scanning Yokes. The set of coils required for magnetic deflection, called a *scanning yoke*, consists of two sets of coils. One, arranged about a vertical axis transverse to the tube axis, produces the horizontal deflection, and another, arranged on a horizontal axis transversely to the tube axis, produces the vertical deflection.

Among the factors on which yoke design depends are (1) the angle of deflection required, which determines the required number of ampere-turns as well as the allowable physical length of the yoke; (2) the necessity of providing a uniform field, to avoid defocusing the spot and distorting the orthogonal shape of the scanning pattern; and (3) the proportioning of the L/R ratio to secure linear deflection with a given deflection amplifier and output transformer.

CONTRAST AND GRADATION OF TELEVISION IMAGES

70. Over-all Brightness Transfer Characteristic. The ability of the television system to reproduce brightness contrasts and tonal gradations is expressed by the over-all brightness transfer characteristic (Fig. 58). The ordinates give the range of bright-
Fig. 58. Brightness-transfer characteristics of a television system.

ness in the reproduced image (image brightness) corresponding to the range of brightness in the original object (object brightness) plotted in the abscissas.

The actual shape of this curve depends on the transfer characteristic (input-output relationship) of each item in the system. In general the actual characteristics cannot be expressed in simple analytic form. However, if an idealization is made, the curves may be expressed in the following form:

$$B_i = B_0 k_0 \gamma_0 \quad (33)$$

where B_i is the image brightness corresponding to the object brightness B_0, k_0 is the proportionality factor relating the image brightness scale to the object brightness scale, and the
FIG. 59. Transfer of object brightness to image brightness through subsidiary transfer characteristics of the elements of a television system.

exponent γ_0 ("transfer slope") determines the extent and direction of the curvature of the characteristics. For unity slope ($\gamma_0 = 1$) the relationship between B_i and B_0 is linear. For slope greater than unity, the curve has an "antisaturation" shape; for slope values below unity, the curve has a "saturation" shape.

The value of slope determines the subjective contrast of the image as viewed by the observer, since the sensation of light in the mind is approximately proportional to the logarithm of the brightness. When Eq. (33) is expressed in logarithmic form

$$\log B_i = \log k_0 + \gamma_0 \log B_0 \quad (34)$$

all the relationships between log B_i and log B_0 become linear and the slope of the lines is directly proportional to the slope value of γ_0. In consequence high contrast is produced by correspondingly high values of slope.

71. Subsidiary Transfer Characteristics. The input-output characteristics of each subsidiary item of equipment in the system can be expressed by a similar relationship:

$$\text{Output} = k(\text{input})^{\gamma}$$

where k relates the scales of the input and output quantities and γ is the slope exponent describing the curvature of the characteristics. By combining each curve in the transmission system successively, equating the output of one device to the input of the succeeding device, it can be shown that the over-all slope of the system is equal to the product of all the subsidiary slopes. In consequence, the effect of one item of equipment whose slope is lower than unity may be compensated by that of another whose slope is the inverse of the first. The slope of iconoscope tubes, for example, lies at about 0.7, whereas that of picture tubes is about 2.5. Assuming that the subsidiary amplifiers, modulators, and demodulators are linear (slope unity), the over-all slope is then $0.7 \times 2.5 = 1.8$; *i.e.*, the slope is somewhat above unity. The orthicon camera, on the other hand, has a slope of unity, and the over-all slope in this case would be 2.5, producing a considerably more contrasty image. The desirable value of over-all slope, following motion-picture practice, is between 1.2 and 1.7. The high value of slope aids in restoring color contrasts lost through the monochromatic nature of the reproduction. It should be noted that high contrasts are limited by picture-tube performance.

The values of the subsidiary slopes also bear on the signal/noise ratio of the system. If a transmitter slope less than unity is employed, most of the picture information consists of signal excursions having amplitudes high on the dynamic characteristic, above the noise. A compensating higher value of slope in the receiver may be used to produce an over-all value within the desirable range of 1.2 to 1.7.

COLOR TELEVISION

72. Compatibility with Monochrome System. The color television standards in use in the United States provide for compatible color and monochrome transmissions. Compatibility is achieved by processing the color signal in such a way that it contains one component which conveys luminance information plus two other components which convey color-difference or chrominance information. The luminance component is very similar to a conventional monochrome signal, and it is transmitted in

such a way that it is capable of producing high-quality images on conventional monochrome receivers. The color-difference or chrominance components are transmitted in the form of side bands around a so-called color subcarrier of 3.579545 Mc. These side bands are simply added to the luminance component of the signal, but the possibility of interference effect is minimized by the use of a technique known as frequency interlace. The chrominance components are ignored by monochrome receivers but are utilized in color receivers, through suitable filters and demodulators, for the generation of signals suitable for controlling red, green, and blue elements in a tricolor display. In the absence of the chrominance components (implying a monochrome transmission), a compatible color receiver automatically produces a monochrome image.

The sections which follow describe the requirement for color-television transmission and reproduction and the means by which these requirements are met.

73. Color Matching. In color television, the system must be able to achieve a match between colors in the original subject and in the televised reproduction. Color matching is greatly simplified by the fact that color perception in the human eye is based on three sets of color receptors in the central portion of the retina. These are sensitive over three contiguous portions of the visible spectrum, centering in the red, green, and blue regions. The spectral sensitivity of each group of receptors may be measured by noting the relative amounts of three spectral primary colors required to match the various colors of the spectrum. Figure 60 shows the relative amounts of standard red, green, and blue spectral primaries required to match each color in the spectrum, based on the "standard observer" of the International Commission on Illumination (ICI).

By so combining three primary colors it is possible to produce a very close match to any color in the spectrum, as well as colors (such as brown, purple, magenta, cyan) which do not occur in the spectrum.

The range of colors over which such matches can be made depends on the number and character of the primary colors used. Two primary colors suffice to match only a very narrow range of colors, while three properly chosen primaries suffice to match closely nearly all the colors that occur in nature. More than three primary colors serve no practical purpose.

A convenient graphical representation of the color-matching process is the color diagram (properly, "chromaticity diagram") shown in Fig. 61. This is a two-dimensional representation of three quantities, x, y, and z, known as the trichromatic coefficients. The quantities x and y are shown explicitly on the diagram, and the z coordinate is given implicitly by the relation $x + y + z = 1$. These quantities specify in normalized fashion the relative proportions of three standard primaries required to match particular colors. A point on the diagram represents one such mixture of primaries and corresponds to the color matched by that mixture. If points are plotted, representing the mixtures required to match each color as it occurs in the spectrum, the points fall on a locus ("spectral locus") shown as a solid line in the figure. The blue colors occur near the origin of the coordinates, the green colors at the top, near the y axis, and the red to the right in the diagram. The spectral locus is closed by a straight line between its extremes. All colors visible to the ICI standard observer may be represented as points in the area bounded by this roughly triangular figure.

The convenience of the color triangle resides in the fact that a straight line drawn between points representing two colors contains points representative of all the colors which can be obtained by combining the two end-point colors in various proportions. Moreover, if three points are chosen and lines are drawn between them to form a triangle, the triangle so formed encloses points representative of all the colors that can be formed by mixing the three apex-point colors in various proportions. In particular, if lines are drawn from an interior point to the apex points, the lengths of these lines are in inverse ratio to the amounts of each apex-point color required in the mixture to match the color represented by the interior point.

The standard ICI spectral primaries (on which Fig. 60 is based) are shown in Fig.

61 as B_s (blue, 435.8 mμ), G_s (green, 546.1 mμ), and R_s (red, 700 mμ). The triangle formed by these points contains all the colors that can be matched by simple addition of these primaries. Although a portion of the area within the spectral locus is not included in the triangle, the portion not included contains shades of green and blue which are not clearly distinguished from one another by the eye, and which in any event do not occur in nature to any extent. The colors included within the three primaries include the vast majority of distinguishable hues and saturations; omission of colors external to the triangle formed by the primaries does not preclude accurate reproduction of colors encountered in practice.
FIG. 60. Relative amounts of standard primary colors required to match spectral colors as per ICI "standard observer."

White light is represented in the central region of the chart. The point marked C represents a standard white (ICI "illuminant C") which closely approximates the color of daylight from the northern sky plus sunlight. Any three colors surrounding this point will, when combined in the proper proportions, match this white. In fact any two colors, the line between which passes through C, will, when properly combined, match this standard white. But such a two-primary system will not match colors off the line and so gives a very poor approximation to nature. For this reason the two-primary system, although occasionally used for motion-picture work, was abandoned in color-television development.

In color photography and television it is not convenient to employ spectral primary colors, which can be obtained only by selecting a narrow portion of a spectrum produced by a prism or grating. Rather, primary colors are produced by passing light through filters, *i.e.*, transparent pieces of colored gelatin, glass, or plastic. These

filters are interposed between the subject and the camera. Standard filters of this type, such as the Wratten series, are widely available.

In a television system, the primary colors used at the transmitter are compounded of three characteristics: the spectral output of the light source, the spectral transmission characteristic of the filter material, and the spectral sensitivity of the photosensitive surface in the camera. At the receiver the corresponding primaries are compounded of the spectral output of the cathode-ray phosphor. The area contained
FIG. 61. Chromaticity diagram showing color gamuts.

by the FCC television primaries is greater than that covered by the photographic transparency processes (Technicolor, Kodachrome, Ektachrome, or Anscochrome). The superiority of the color gamut of the television system over printing inks, pigments, etc., is readily apparent in Fig. 61.

74. Color Balance. In accordance with modern television practice, *luminance* is a measure of the light flux emitted, reflected, or transmitted per unit solid angle per unit projected area of the source. The usual units are lamberts, foot-lamberts, or candles per square foot. This quantity is also called *photometric brightness.*

Brightness is defined as the attribute of visual perception in accordance with which an area appears to emit more or less light.

The use of these terms permits "brightness" to be used entirely with reference to the sensory response. A photoelectric instrument calibrated in foot-lamberts would not be referred to as a "brightness" meter. If correctly calibrated it is a "luminance" meter.

In color reproduction it is necessary that the color match between an original subject and the televised reproduction be correct over the range of luminance present in the original scene, and also that the colors appear relatively correct when the luminance range of the reproduction is substantially less than that of the original scene. The color-matching process represented in the color diagram applies over a wide range of absolute luminance. As an example, consider that a given blue is matched by a specific mixture of primaries. If the luminance of the blue is substantially increased so that it appears to be blue-white, the same mixture of primaries will match the blue-white, provided only that the luminance of each primary is correspondingly increased in proportion.

To achieve color balance over a range of luminance the intensity of the primaries must vary in proportion to the luminance of the original color. Thus, if the transfer characteristic that applies to the green primary does not have the same extent and shape as those applying to the red and blue, correct color matching would be achieved only over a restricted range of luminance. To avoid this restriction, dynamic-control amplifiers may be employed to match the shape and extent of all the transfer characteristics. To permit accurate delineation of colors over a range of luminance, it is required that all three transfer characteristics be linear, *i.e.*, the log of each receiver primary luminance should be a linear function of the log of the corresponding transmitter primary luminance.

A critical test of the ability of a color-reproduction system to maintain color balance is the transmission of a gray scale, *i.e.*, a series of gray patches having steps of luminance in logarithmic progression. Lack of color balance is revealed by the presence of color in one or more of the patches of the reproduced scale. Adjustment of the transfer-characteristic control amplifiers to remove any color tinge from the steps of the gray scale is then indicated.

75. The Color Subcarrier Frequency. For reasons which will be explained, the FCC color-television standards specify a horizontal scanning rate of 15,734.264 cps and a vertical field rate of 59.94 cps, instead of the monochrome rates of 15,750 and 60 cps.

The color subcarrier frequency of 3.579545 Mc is spaced less than 4 Mc from the video carrier. If the color subcarrier frequency were slowly changed, it would be observed on a picture monitor that the beat-note interference would vary widely in visibility. The subcarrier frequencies at which the beat pattern is minimized are odd multiples of half the horizontal line frequency. One half of the color line frequency of 15,734.264 is 7,867.132 cps. The 455th multiple of this frequency is 3.579545 Mc. During each horizontal line there are 227.5 cycles of video carrier-color subcarrier beat. Since each cycle represents two changes of light intensity, there are 455 variations of brightness per line.

Upon the completion of one field scan, the phase of the beat note reverses 180 deg because the color subcarrier is an odd multiple of half the line frequency. As a result the lines of the following field contain a beat-note pattern having the amplitude variations reversed. Since the persistence of vision of the human eye is long compared with these brightness changes, they blend and the eye sees only the average fine-detail brightness. To all intents the beat pattern is invisible. Since there are an odd number of beat-frequency light variations per line, they are staggered on successive lines. This provides added cancellation.

Another possible source of beat-note interference is present between the color subcarrier and the sound carrier. The difference in frequencies is only slightly over 900 kc and the interference produced would be very objectionable. This may also

be minimized by frequency interlace but to do so and also maintain frequency interlace with the video carrier frequency it is necessary to reduce the field rate from 60 to 59.94 and the line rate to 15,734.264 as stated at the beginning of this section. These small changes in transmission standards between monochrome and color transmission and reception are well within the system tolerances and introduce no problems. Figure 62 illustrates the manner in which frequency interlacing produces beat-interference cancellation.

76. Suppressed Subcarrier Transmission. The United States color standards employ suppressed subcarrier transmission through the use of color subcarrier balanced modulators. Since only the color side-band energy is transmitted, no subcarrier signal is present when the camera scans a black, white, or gray object. Also, when scenes of low color saturation are scanned by the color camera, the energy in the color side bands is correspondingly low. This feature aids materially in the suppression of beats between the color signal and the sound signal because the subcarrier signal is present only when color-difference information is actually being transmitted, and is of low amplitude for colors of low or intermediate saturation.

FIG. 62. Manner in which beat interference is minimized by frequency interlacing.

77. Color Information Transmitted. Highly satisfactory color reproduction may be accomplished through proper mixtures of the red, green, and blue primary colors. Good color reproduction also could be obtained if other primary colors were adopted so long as no one of the primaries could be produced by any combination of the other two. The luminance of a picture consists of the integrated luminances of the three colors of which it is composed. In the United States color-television system the receiver picture tube is fed by a luminance component accompanied by color components of red, green, and blue. However, the signal transmitted, prior to the receiver matrix, consists of only a luminance and two color-difference (chrominance) components. The color components may be eliminated to leave only the luminance achromatic component, which was the only form of television picture transmitted and received prior to the advent of color television. A black-and-white television camera scanned colored images but selected only the luminance component, rejecting the color components.

The reproduction of a colored scene on a monochrome reproducing system requires, for most natural rendition, that the proper luminance values of each of the three primary colors be transmitted and reproduced. In a color system, substantially equal parts of red, green, and blue are arbitrarily equated to the amount needed to match a specified white. Because of the characteristics of our eyes and brain, red, green, and blue colors of corresponding luminance values do not appear to us to be equally bright. A monochrome system sees everything as black or white or a shade of gray. Viewers in their homes do not see the original object but only a reproduction of it. The hue and saturation of costumes, scenery, and background objects may vary widely at the discretion of the television producer. Considerable latitude is possible in creating the scene desired. Therefore, the precise reproduction of the luminance values of such objects is not highly important. A desirable range in
brightness contrast between objects is more important to separate the parts of the scene being viewed. However, in transmitting flesh tones, large inaccuracies in reproducing the luminance values of red, green, and blue may give an unnatural emphasis to facial features which is noticeable to viewers familiar with relatively uniform facial characteristics.

Equal luminance values of saturated red, green, and blue colors produce a brightness sensation to the human seeing mechanism of 59, 30, and 11 per cent, respectively. The use of these values in the United States television system for the luminance components of color pictures produces a natural and satisfactory reproduction on monochrome receivers. These values were chosen to facilitate the use of the constant-luminance principle. The choice of these coefficients for the monochrome signal facilitates the use of gains in the receiver which minimize the effects of sine-wave interference in the color channels. Horizontal bars caused by such interference would have color values in a color receiver but the brightness value would be minimized. Similarly, the visibility of high-frequency thermal noise or high-frequency components of the brightness signal which enter the receiver decoders are minimized. This follows from the constant-luminance principle upon which the United States system is based. In this system signals in the color subcarrier channel have very little effect upon the luminance of the reproduced picture. The luminance is almost completely controlled by the picture carrier channel, not the color subcarrier channel.

The constant-luminance principle takes advantage of the fact that the eye is much more sensitive to luminance variations than to color variations. The adjustment of the luminance coefficients in the system is accomplished by control of the gain of the separate amplifiers which amplify the outputs of the red, green, and blue cameras.

The luminance component of a color picture is transmitted independently by modulation of the picture carrier. The color components are transmitted as color-difference signals by modulation of the color subcarrier. A color-difference signal is one which, when added to the monochrome signal, produces a signal representative of one of the tristimulus values (with respect to a stated set of primaries) of the transmitted color. A blue color-difference signal voltage may be obtained from the blue camera tube by subtracting from it the voltage of the luminance signal. Similar operations may be performed at the output of the red and green camera tubes to obtain the red and the green color-difference signals. However, it is not necessary to transmit the separate red, green, and blue components to reproduce tricolor pictures. It is only necessary to transmit the luminance component and two color-difference subcarrier components. This technique is employed. By limiting the amount of information transmitted to only the essential ingredients, which in the United States system are the luminance and two color-difference components, the system attains maximum simplicity and spectrum economy. The two color components are transmitted by modulation of the color subcarrier in a manner to be described.
FIG. 63. Two-phase modulating system employing separate amplitude-modulated carriers displaced 90 deg. This is equivalent to having simultaneous amplitude and phase modulation of a single carrier.

78. Modulation of Color Subcarrier. The luminance component is transmitted by amplitude modulation of the video carrier. Two color components must also be transmitted. It is not possible to employ two separate modulated color subcarriers of different frequency satisfactorily because there would be a difference of frequency between them which would be an even multiple of one-half the line frequency. This would not be frequency-interlaced and, therefore, the interference beat-note pattern would not be self-canceling. Any nonlinearity in the system such as exists, for example, in picture tubes would produce this beat note representing the difference frequency between the two subcarriers. This difficulty is avoided by the use of two-

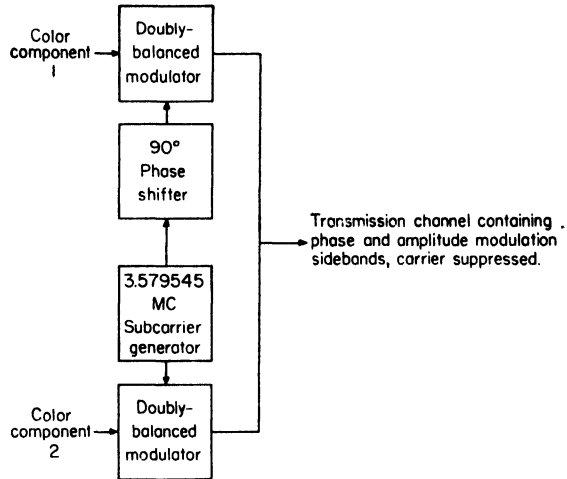
phase modulation of a single subcarrier. This two-phase modulation is accomplished by using two subcarriers of identical frequency but displaced in phase by 90 deg as shown in Fig. 63. In practice the two subcarriers are produced from a single source with two branched outputs. On one the phase is unchanged and on the other it is shifted 90 deg. Figure 64 is a block diagram of the modulating system. The output of this two-phase modulating system is the vector sum of the two quadrature-related and separately amplitude-modulated subcarriers of the same frequency. In the resulting vector sum, the amplitude of the modulation products is a function of color saturation while the resulting phase represents hue. At the receiver the two color components may again be separated and re-created by synchronous demodulators. The in-phase a-m signal is demodulated by applying to the synchronous detector an unmodulated 3.579545-Mc subcarrier of the same phase as was used in the original amplitude modulation. The quadrature-phased modulated signal is demodulated in the same manner except that the subcarrier is shifted 90 deg to correspond exactly to the phase in the original modulation. This imposes the requirement that there must be available at both transmitter and receiver subcarrier voltage of identical frequency and phase. It is impractical to attain such precise control of unmodulated subcarrier frequency and phase by the use of a free-running subcarrier oscillator at the receiver. Therefore, a means is required to control precisely a receiver subcarrier oscillator from the original 3.579545-Mc transmitter oscillator. This is accomplished by transmitting bursts of unmodulated subcarrier power from the transmitter to the receiver where it locks the frequency and phase of the receiver oscillator.


Fig. 64. Block diagram of two-phase subcarrier modulating system.
Fig. 65. Subcarrier burst as transmitted on horizontal blanking pedestal.

79. Subcarrier Burst. The subcarrier bursts are transmitted by modulation of the horizontal blanking pedestal as shown in Fig. 65. From 8 to 11 cycles are transmitted. The burst voltage is suppressed at other times. The insertion time and interval are controlled by an electronic gate which is in turn keyed open by burst flag pulses derived from the horizontal deflection circuits. At the receiver a similarly controlled pulse gate isolates the subcarrier bursts from all other voltages at times when the burst is being transmitted and received. By example, a block diagram of a demodulating system is shown in Fig. 66. It may be noted that the receiver subcarrier oscillator phase is locked to the burst phase by means of a phase detector and reactance tube.

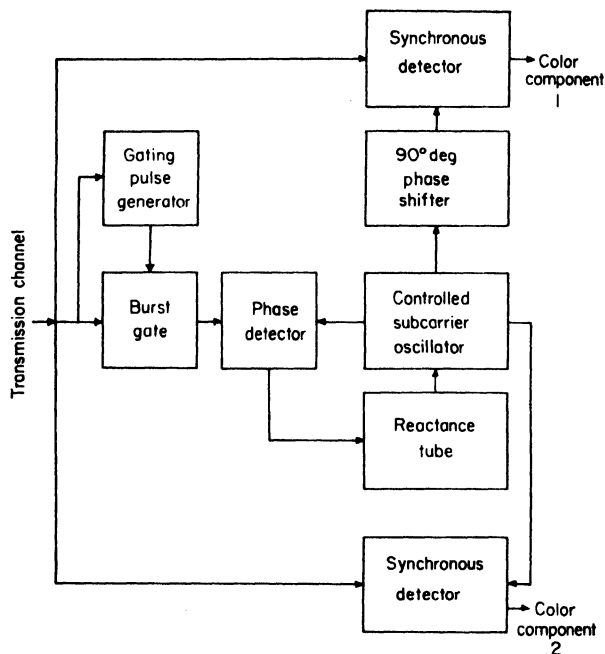
In these circuits the burst and the oscillator phases are compared in the phase detector. Any difference produces a succession of pulses which occur at the gating frequency. These are filtered to produce a d-c control voltage which causes the reactance tube to correct the oscillator phase within a few degrees.


FIG. 66. Block diagram of a two-phase subcarrier demodulating system.

80. Synchronous Detectors. When suppressed carrier transmission is employed and only the modulation side bands are transmitted, the original modulating signal may be re-created only if a locally generated carrier is added at the receiver detector. The carrier added must be of the same frequency or synchronous with the suppressed carrier, and, for full utilization of both side bands, the phases must also correspond. This type of detection, in which a synchronous locally generated carrier is added to incoming side-band energy, is called synchronous detection. If the locally generated carrier is in quadrature with the suppressed carrier, the upper- and lower-frequency side bands do not add. They are in effect shifted +90 deg in one case and −90 deg in the other and cancel, producing no output. The two-phase modulating system described above depends upon this characteristic. The side bands of color component No. 1 produce normal demodulated output when combined with a locally generated carrier corresponding in phase to the original carrier, but produce no output when combined with a carrier rotated 90 deg, such as that of color component No. 2. The reverse is true. The United States standards of color television permit the use of this principle. If the two sets of side bands correspond in band width and both sets of side bands are transmitted normally for both color components, no cross talk between channels occurs. However, if on one channel the upper or lower side bands were missing or attenuated, complete cancellation would not occur when combined with the phase-shifted carrier of the other channel, and cross talk would then occur. In the United States system, one color channel employs vestigial-side-band transmission by attenuation of the highest-frequency components. However, in this

case cross talk is prevented by band-limiting the opposite channel so that the attenuated side-band frequencies are prevented from reaching the synchronous detector.

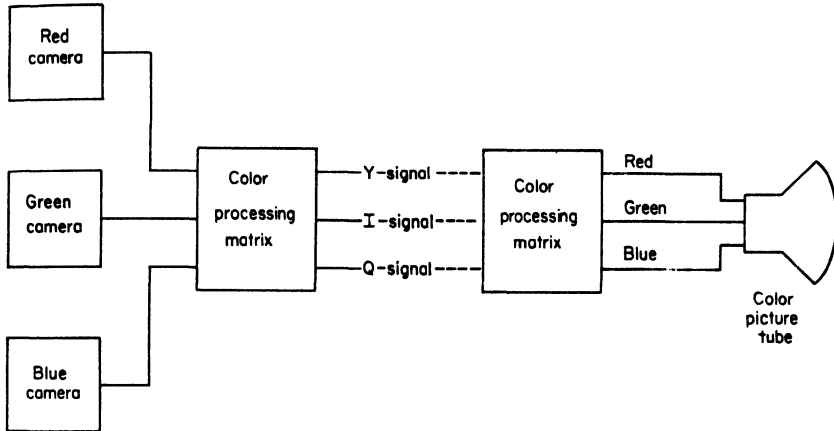
81. *I* and *Q* Signals. The in-phase color component which is transmitted is referred to as the *I signal* and the quadrature component as the *Q signal*. The brightness component is referred to as the *Y signal*. The outputs of the red, green, and blue cameras are fed to a color-processing matrix in which the three voltages are combined in proper proportions to produce the *Y* signal and also the separate *I* and *Q*


FIG. 67. Method by which camera-output signals are processed for transmission and restored in reception.
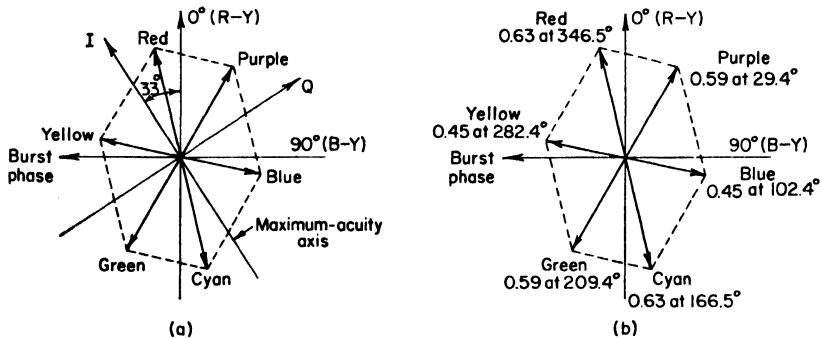

FIG. 68. (*a*) Vector diagram showing axis corresponding to maximum acuity for human vision. (*b*) Subcarrier phases and amplitudes for six colors.

signals. This is illustrated in the simplified diagram in Fig. 67. At the receiver a corresponding matrix may be employed for restoring the red, green, and blue signals.

The *I* and *Q* vectors, when modulated, may be considered to produce a resultant vector sum. These vectors may be reversed in polarity. Thus, in combination, the sum of these vectors may have any phase from 0 to 360 deg. The phase corresponds to the color, or hue, of the signal transmitted and received. The amplitudes of the *I* and *Q* signals which vary separately produce changes in the amplitude of the vector sum. The amplitude is a function of the saturation of the color transmitted and received.

Figure 68 shows the group of colors produced by the FCC approved signal-standards color system when the phase of the reference color burst signal properly corresponds with

the correct axis as shown. The I signal is fixed on the orange-cyan axis and the Q signal, lagging 90 deg, is fixed on the purple-yellowish-green axis. The orange-cyan axis was selected for the I signal to take advantage of the spectral sensitivity of the human eye which is most acute for these colors. Fine detail may be most clearly detected on this axis. The band width of the I-signal channel was established to conform with the amount of detail the eye can distinguish on this axis under normal viewing conditions. It is specified as follows:

At 1.3 Mc less than 2 db down
At 3.6 Mc at least 20 db down

The useful band width is approximately 1.5 Mc.

The eye has less acuity for colors on the Q-signal axis and the specification is as follows:

At 400 kc less than 2 db down
At 500 kc less than 6 db down
At 600 kc at least 6 db down

The useful band width is approximately 500 kc.

These specifications accomplish two important objectives. First, they provide adequate color detail for those colors to which the eye is most sensitive and restrict the band width to useful dimensions for colors to which the eye is insensitive in fine detail. Thus, the minimum necessary band width is employed. Second, they make it possible to utilize vestigial-side-band transmission of the 1.5-Mc I signal in combination with a relatively high subcarrier frequency, without cross talk with the Q channel.

Attention is directed to the fact that the subcarrier frequency of 3.579545 Mc is only 0.57 Mc below the frequency of 4.15 Mc at which the video response of the receiver must cut off. Two narrow color channels of about 0.5 Mc could be employed with symmetrical side-band transmission without cross talk; but, if the channels were increased in band width to the point where the upper side bands were attenuated, cancellation of the quadrature side bands between the I and Q channels would not take place and cross talk would result. By restricting the band width of the Q channel to 0.5 Mc so that side-band attenuation does not occur and the unsymmetrical side bands from the I signal are rejected, the wide-band I channel may be employed without cross talk.

The I signal may be obtained in a roundabout manner, not ordinarily employed, from the vector sum of signal vectors from the red and blue cameras. After the brightness component is removed to produce the $E_R - E_Y$ and the $E_B - E_Y$ color-difference signals, they are combined to produce the E_I signal in the following proportions.

$$E_I = -0.27(E_B - E_Y) + 0.74(E_R - E_Y) \qquad (35)$$

It will be noted that the polarity of the $E_B - E_Y$ signal was inverted to produce the proper I-signal phase of 57 deg corresponding to orange. Inversion of the phase is accomplished by passing the signal through a plate-coupled amplifier stage. Apportioning of the red and blue color-difference signals is accomplished by voltage-dividing resistors. The inverted $E_B - E_Y$ signal corresponds to the color which is complementary to blue, which is approximately yellow.

Following the creation of the I signal, it is passed through a filter which limits the band width to about 1.5 Mc, as explained previously.

The Q signal by this method would be correspondingly produced by combining certain proportions of the red and blue color-difference signals. Since the Q vector lies between the red and blue vectors, no inversion is necessary. The Q-signal specification is as follows:

$$E_Q = 0.41(E_B - E_Y) + 0.48(E_R - E_Y) \qquad (36)$$

The vector sum of these vectors corresponds to the color reddish-blue or purple. The color complementary to this, yellowish-green, is obtained by reversing the polarity of the Q signal which is accomplished by reversing the polarities of the red and blue color-difference signals of which it is composed. The Q signal is passed through a filter which limits its band width to about 0.5 Mc.

Figure 69 shows how the video spectrum is utilized in the simultaneous transmission of the luminance signal, the vestigial-side-band I signal, and the double-side-band Q signal.

The equations for the I and Q signals were shown, in terms of the red and blue color-difference signals, to be

$$I = 0.74(R - Y) - 0.27(B - Y) \qquad (37)$$

$$Q = 0.48(R - Y) + 0.41(B - Y) \qquad (38)$$

The equation for the brightness signal was shown to be

$$Y = 0.30R + 0.59G + 0.11B \tag{39}$$

It may be proved that the green component is present by substituting in the I and Q equations the color values representing the brightness signal. Solving these equations gives the following components for the I and Q signals, which are equivalent to Eqs. (37) and (38):

$$I = 0.60R - 0.28G - 0.32B \tag{40}$$
$$Q = 0.21R - 0.52G + 0.31B \tag{41}$$

This operation illustrates that the I and Q signals may be produced at the camera output without the intermediate step of producing the red and blue color-difference signals. This is the simpler method conventionally employed. It may also be shown that the red and blue color-difference signals may be obtained by cross-mixing the I and Q demodulator outputs, by solving the I and Q equations for the red and blue color-difference signals expressed as components of I and Q. They are

$$B - Y = 1.7Q - 1.1I \tag{42}$$
$$R - Y = 0.62Q + 0.96I \tag{43}$$

In practice, all three color-difference signals may be abstracted from the received signal by appropriate demodulation.

The complete color-picture signal has the following composition:

$$E_M = E_Y' + [E_Q' \sin(\omega t + 33 \text{ deg}) + E_I' \cos(\omega t + 33 \text{ deg})] \tag{44}$$

where E_Y', E_Q', and E_I' are the gamma-corrected signals, E_M is the total video voltage corresponding to the scanning of a particular picture element, and ω is 2π times the subcarrier frequency.

Fig. 69. Simultaneous utilization of video spectrum by luminance, I, and Q channels in FCC Standards for Compatible Color Television.

For color-difference frequencies below 0.5 Mc, the signal may be represented by

$$E_M = E_Y' + \left\{\frac{1}{1.14}\left[\frac{1}{1.78}(E_B' - E_Y')\sin\omega t + (E_R' - E_Y')\cos\omega t\right]\right\} \tag{45}$$

82. Color-burst Phase. It will be noted from Fig. 68 that the phase of the color burst differs from that of the I-signal axis by 57 deg and not 90 deg, and from the Q-signal axis by 147 deg instead of 180 deg. Tests showed that certain burst phases produced minimum visibility in the return trace but simultaneously they also adversely affected d-c restoration. No compelling reasons exist for rotating the burst phase from 57 deg, but an advantage would accrue in cost savings in manufacturing inexpensive color receivers which did not take full advantage of the maximum possible color detail provided for in the standards. In such inexpensive receivers, for example, the $R - Y$ and $B - Y$ signals (instead of I and Q) could be used, each having a band width sufficiently narrow (not more than about 0.5 Mc) so that matrixes would be simplified and cheapened, and cross-talk problems resulting from vestigial I-signal side-band transmission could be eliminated.

83. Delay Circuits. From the output of the color cameras the Y signal is produced directly by combining the red, green, and blue voltages in proper proportion in a simple resistance network. However, the I and Q signals pass through band-limiting filters. When a signal passes through a limiting filter, it is delayed in time. The delay is greatest when the band limiting is greatest. Therefore, unless corrective steps were taken the Y signal at the receiver would arrive first, followed next by the I signal and last by the Q signal. When combined and viewed on a picture tube, the color information would be displaced from the brightness information in the horizontal plane and poor vertical edges would result. To cause the Y, I, and Q signals to coincide in arrival time, delay networks are added in the I and Y channels at the transmitter to equalize the delays. The delay introduced in the Y channel is about 1 μsec.

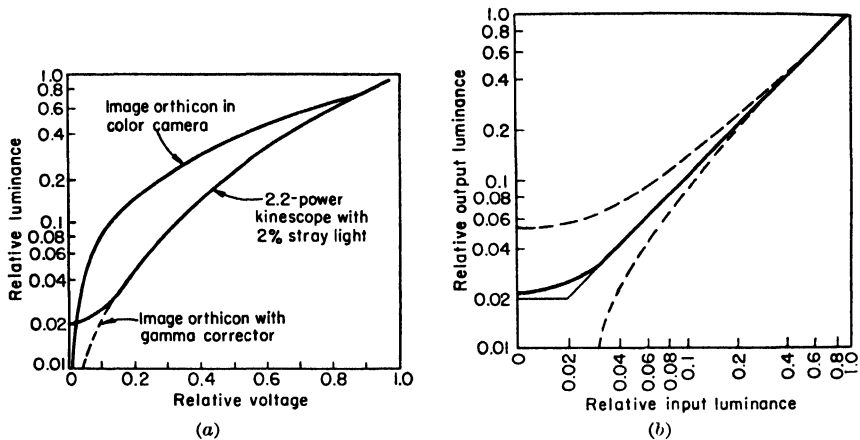
84. Gamma Correction. The linear relationship of the light-input values at the camera tube and the light-output values at the receiver tube is one measure of the


FIG. 70. (a) Plot comparing a color-camera image orthicon curve with that of a 2.2-power kinescope with 2 per cent stray light. (b) Over-all transfer characteristics for a corrected-color-image orthicon camera driving a 2.2-power color kinescope with 2 per cent stray light. The slight "toe" on the characteristic results from failure to achieve an infinite slope in the gamma corrector. Dotted lines show curves for 5 per cent and zero stray light conditions with no change in relative bias.

fidelity of the system but in monochrome transmission considerable tolerance has been permissible. In color transmission the situation is quite different, because reproduced color fidelity depends upon the combinations of three voltages from three separate color-camera tubes which operate at random over wide amplitude ranges. There must be gamma correction to compensate for the nonlinear relationship between input voltage and light output of receiver picture tubes, as in monochrome television. But there must also be a close match between the transfer characteristics of the three color channels. A difference in the response between these channels destroys the relationships of the voltages which must combine in the correct proportions for true color reproduction. In addition, this may produce incorrect color values at various places on the brightness or saturation range.

By a wide margin the most essential phase of gamma correction is obtaining equality in the three primary color channels at all operating amplitudes. Lack of it produces noticeable and objectionable errors in chromaticity and will be especially objectionable when white should be reproduced.

Gamma correction is an essential part of the color-transmitting system and is accomplished in gamma-correcting circuits at the outputs of the red, green, and blue

camera tubes. Figure 70*a* from Wentworth compares the characteristics of a color-camera image orthicon tube and a 2.2-power kinescope with 2 per cent stray light. Figure 70*b* shows the over-all gamma-corrected characteristic.

85. Phase Distortion and Compensation. The FCC standards specify a transmission frequency response characteristic and a corresponding receiver characteristic as shown in Fig. 41. In this system there are sources of phase distortion and associated envelope delay. Unless compensation is introduced, the envelope delay through the system is sufficient to produce noticeable picture degradation.

The sharp receiver cutoff at about 4.1 Mc produces phase shift which is not proportional to frequency and becomes objectionable above about 2.5 Mc. The resulting overshoots following sharp vertical edges produce ringing and smear. This effect is minimized by phase correction which distributes the overshoot in a sym-
FIG. 71. Envelope delay specified to compensate for vestigial-side-band filter and receiver high-frequency cutoff.

metrical manner about the transition point and reduces the amplitude about 50 per cent.

The vestigial-side-band filter attenuation produces envelope delay which is decreasingly significant at frequencies up to about 3 Mc. This shows as a leading undershoot and loss of sharpness of vertical edges. Compensation minimizes the undershoot and resulting smear.

The United States standards specify that a sine wave introduced at those terminals of the transmitter which are normally fed the composite color-picture signal shall produce a radiated signal having an envelope delay, relative to the average envelope delay between 0.05 and 0.2 Mc, of zero microseconds up to a frequency of 3 Mc and then linearly decreasing to 4.18 Mc, so as to be equal to -0.17 μsec at 3.58 Mc. The tolerance on the envelope delay shall become ± 0.1 μsec at 2.1 Mc and remain at ± 0.1 μsec down to 0.2 Mc. The tolerance shall also increase linearly to ± 0.1 μsec at 4.18 Mc. This specification is illustrated in Fig. 71. The tolerance of ± 0.05 is equal to about one-half of a horizontal picture element.

The over-all color-transmitting system incorporating the elements which have been described is illustrated in simplified manner in Fig. 72.

86. Color-television Receivers. Many variations of circuitry are possible in receivers designed to United States color standards. Figure 73 shows, for example, various circuit arrangements that have been used. The first detector is omitted from the diagram for simplicity. From the second detector one circuit drives the sound system similar to those in monochrome receivers. Another circuit from the second detector may drive a video amplifier No. 1, having two outputs. One contains a delay line for correction of time delay of the luminance signal. This output does not transmit the 3.579-Mc subcarrier. It contains a contrast control and supplies brightness information to the adders. The other output from video amplifier No. 1

contains another contrast control mechanically actuated on a common shaft with the one referred to. This control drives a band-pass chroma amplifier, No. 2, which may be band-limited to 1.5 Mc in the chroma output. A chroma-voltage control from this output drives the *I* and *Q* demodulators.

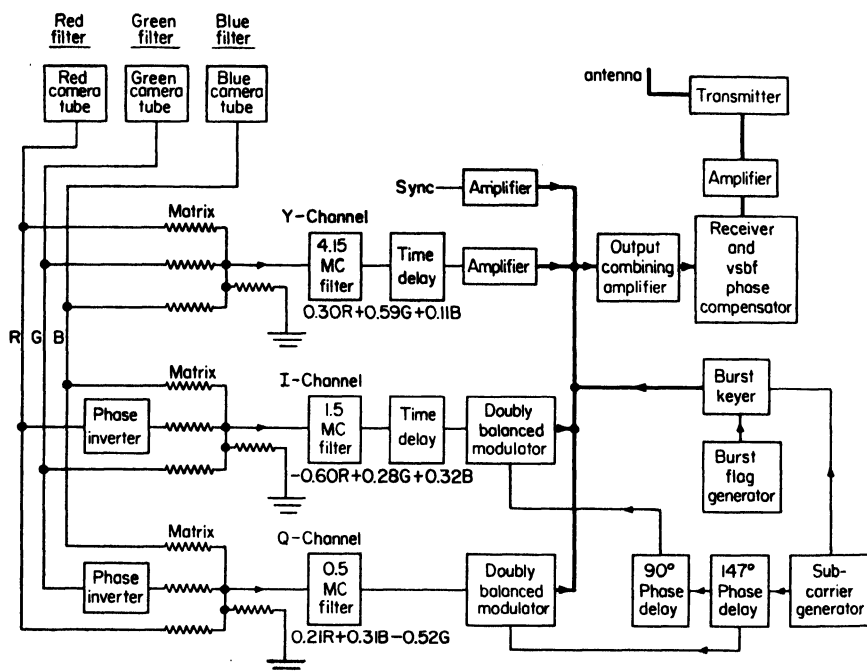
From amplifier No. 1, 3.579-Mc subcarrier burst voltage is fed to a burst amplifier, phase detector, reactance tube, and subcarrier reference oscillator which in combination lock the phase of the latter unit to that of the subcarrier oscillator at the transmitting point of origination. The color subcarrier reference oscillator utilizes only the burst portion of the chroma signal. Burst gate pulses from the horizontal deflection system admit the bursts but block out all other components of the incoming signal


FIG. 72. Elements of a color-transmitting system.

at the burst amplifier. From the reference oscillator subcarrier voltage is fed directly to the *I* synchronous detector. Also, through a 90-deg phase shifter, subcarrier voltage is fed to the *Q* synchronous detector. The *Q* channel, as shown, is band-limited by a 0.5-Mc low-pass filter and the *I* channel is similarly limited to 1.5 Mc.

During transmission of monochrome pictures it is desirable to disable the color channels so that only the output of the brightness channel is present in the adders. This disabling then eliminates noise or high-frequency monochrome signal components from the adders where they could generate spurious low-frequency color-voltage components. The disabling is accomplished by a color killer. When burst voltage is received it provides a voltage which overcomes the cutoff bias voltage otherwise present on amplifier No. 2.

The brightness and synchronizing deflection circuits are very similar to those in monochrome receivers. One circuit may provide AGC voltage for the r-f and i-f systems by deriving the AGC voltage from the horizontal deflection system, as shown. This method of AGC provides the close distribution of control which is more important in color receivers than monochrome.

A color receiver essentially differs from a monochrome receiver by the addition of color-processing components which have no counterpart in monochrome receivers. These components, as represented in Fig. 73, are the *I* and *Q* quadrature color channels, the reference subcarrier oscillator and its auxiliaries, the matrixes, and the adders which combine the brightness and the color voltages.

Two important alternatives in color-receiver detector design are employed. In one, as illustrated in Fig. 73, the brightness, color, and sound signals are taken from a common second detector by means of v-f selective circuits. In the other, the last i-f stage or stages contain branches with two or three second detectors, each of which is followed by its own selective circuits and amplifiers. A single detector may function for the brightness and sound signals or, in alternative designs, for chrominance and sound.

FIG. 73. Principal components of circuitry of one form of a color-television receiver following the second detector. Main signal channels have heavy lines for easy identification.

Receivers have been used commercially which take full advantage of the 1.5-Mc *I*-signal band width. However, as indicated previously, the incoming chrominance information may be band-limited in each channel to 0.5 Mc or less into the $R - Y$ and $B - Y$ signals, at some reduction in cost, circuitry, and color detail. In either case the outputs of the matrixes are $R - Y$, $G - Y$, and $B - Y$.

It is desirable to maintain the superheterodyne local oscillator frequency within 50 kc when employing a single brightness-color detector to keep the sound-channel frequency in the minimum response area of the sound-suppression notch. Excessive frequency drift will increase the amplitude of the sound voltage in the picture circuits and correspondingly increase the amplitude of the sound-subcarrier beat note of 920 kc. This cannot be eliminated in the brightness amplifiers. It must be controlled by reducing the sound i-f level. It is proportional to the product of the i-f chrominance subcarrier and the i-f sound carrier. For satisfactory suppression of the beat voltage it is customary to maintain it 40 db below the brightness-signal level.

87. Tricolor Kinescope. The RCA type of shadow-mask color-picture tube is used in all color receivers now produced. Three electron guns are employed, one each for red, green, and blue. The electron streams converge at a perforated masking plate, as shown in Fig. 74*a* and *b*. After passing through a perforation the beams diverge and impinge upon separate phosphor dots which, when so excited, produce the red, green, and blue light corresponding to the individual exciting electron beams. One set of red-, green-, and blue-emitting phosphor dots is located in a triangular configuration behind each perforation. Current tubes contain 356,666 perforations and sets of dots, representing a total of 1,070,000 dots. The three electron beams are individually focused and, by an electrostatic-lens system, are made to converge at the aperture mask or screen. They are electromagnetically deflected in the horizontal and vertical planes simultaneously by a common yoke. Convergence at a common point is produced by separate convergence controls.

Dynamic convergence controls are also provided. The reason is illustrated in an exaggerated degree by reference to Fig. 74*c*, which shows an earlier type of color kinescope having a flat shadow-mask plate. An adjustment which produced correct convergence control at point *A* would not have been correct for point *B*. Therefore, dynamic convergence control is provided to correct for the changing focal distance as the beam travels from top to bottom and across the plate. This is accomplished by the application of parabolic wave forms to the convergence circuits, obtained from the horizontal- and vertical-deflection circuits. Although the modern curved masked kinescope shown in Fig. 74*a* has more nearly uniform focal distance as the beam traverses, it is not entirely uniform. Figure 74*c* is included only to illustrate in exaggerated form the effect described.

The shadow-mask holes and dots are so positioned that the electron beam from, for example, the green gun can strike only green-emitting dots and, similarly, the red and blue beams strike only red- and blue-emitting dots. The intensity of the light from the individual dots is controlled by the beam intensities, which are in turn controlled by the individual gun grids. The eye automatically integrates the colors and their intensities to recreate the original picture content. White light is observed by the eye at any reasonable viewing distance when the proper ratio of red-, green-, and
FIG. 74. Shadow-mask color kinescope.

blue-dot excitation is produced, despite the fact that close inspection shows only red, green, and blue dots.

TEST AND ALIGNMENT PROCEDURES

Faithful transmission and reproduction of television pictures require that the adjustment of the components of the complex system be correct. Standard test procedures are necessary so that the performance of the system or its components may be evaluated simply and rapidly. Certain fundamental parameters require special attention.

88. Amplitude Response vs. Frequency. The gain of the system should be uniform over the v-f range. In color transmission in particular a difference in gain in the area of the color subcarrier will change the amplitude of the color components compared with the brightness signal and the reproduced color will be too low or too high in saturation. To evaluate this characteristic of the system a multifrequency burst signal may be used. Such a generator produces its own line-frequency blanking and synchronizing signal. No vertical signal is necessary. The trailing edge of the blanking signal triggers a chain of six multivibrators which function in sequence to introduce or key-in during each line interval a choice of six different video frequencies. These are transmitted in succession at equal amplitude and are reproduced at the terminal point on an oscilloscope. The output may be observed visually and may be photographed on a Land camera from which the complete print is available in 1 min. The wave form of the burst signal is shown in Fig. 75. Built-in oscillators are used to generate each of the six frequency bursts and each of these oscillators is variable over a range of frequencies. The sequence may be, for example, 0.5, 1.5, 2.0, 3.0, 3.6, and 4.2 Mc. An oscilloscope is used not only at the terminal point but also at the transmitting point to monitor the signals and adjust levels. The response of the system at each frequency may be compared with the blanking and sync signal

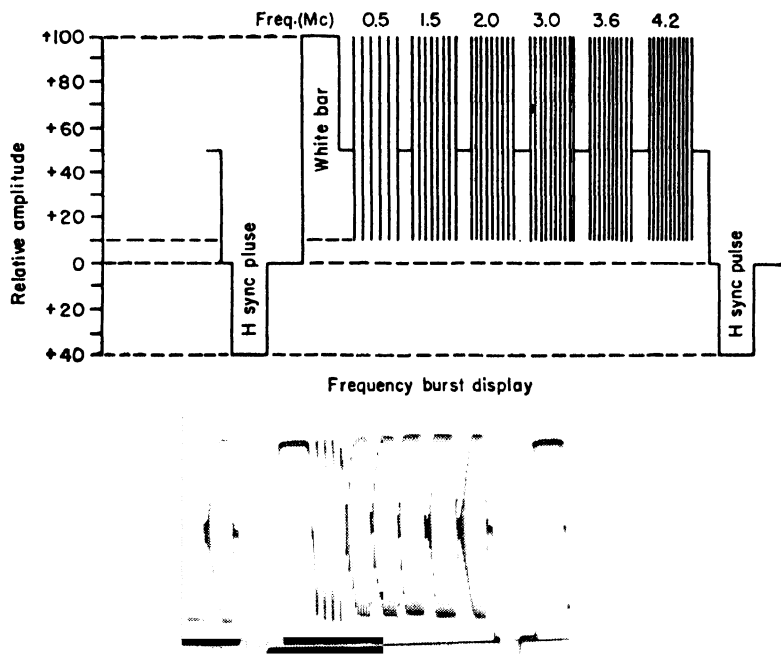
and with the other frequencies, and also with a white bar which is transmitted just prior to the first sine-wave burst. Nonlinear amplitude response may be observed when present at any burst frequency. Harmonic distortion may be observed by expanding the oscilloscope scale, particularly at the lowest burst frequencies.


FIG. 75. Multiburst signal and CRO wave-form display.

89. Smear and Streaking. Streaking is produced by irregular frequency responses, usually at the low and middle video frequencies. Because of the system clamping circuits it is seldom present below 60 cps and in practice it is usually below 200 kc, at line frequency or multiples of it. This irregularity may be observed on an oscilloscope by transmitting and observing a white window signal such as is shown in Fig. 76. It may also be observed on a picture monitor. Streaking may be positive when a white streak follows a white image, or negative when a white streak follows a black image, or it may be a combination of both. With the oscilloscope adjusted for the horizontal rate, streaking will appear as low-frequency undershoots or overshoots to the rectangular white window signal and these usually may be seen to be sine waves or parts of sine waves added to the horizontal flat top of the window or the setup line. By observing the horizontal interval of the sine-wave addition, its frequency may be estimated by comparing it with the line frequency of 15,750 kc. The window signal is produced by a generator containing adjustment for control of window size. To produce sensitivity to low-frequency irregularities, the window is often made large, about half of picture height and width. A video resonant circuit in the transmitting system will produce ringing which will be visible on picture tubes as a series of closely spaced images displaced to the right of vertical lines. The amplitude and frequency of the irregularity may be evaluated closely by observing the window signal on an oscilloscope. The window signal contains both horizontal and vertical sync signals.

90. Amplitude and Phase Linearity. A stair-step signal is used to test and evaluate amplitude and phase linearity, which are referred to as differential gain and differential phase response. Usually 10 equal steps are transmitted ranging progressively from black level to white level as shown in Fig. 77. In reproduction, differences in the amplitudes of the steps indicate nonlinear amplitude response. Superimposed upon each step there may be sine waves of color subcarrier frequency having on each step an amplitude of about twice the step amplitude. If the latter composite signal is passed through a filter which eliminates the frequencies below the subcarrier, the subcarrier components of each step are then lined up horizontally on the same axis. A difference in amplitude between the 10 subcarrier segments, now shown side by
Fig. 76. White-window signal and CRO display.

side, indicates that the gain of the system differs over the amplitude range, and shows also the portion of the range where it exists.

The measurement of differential phase is made by comparing the phase of the individual subcarrier segments with a reference phase. A calibrated phase shifter is employed to measure the degree of phase departure, by observing the amount of phase shift required to make the reference phase coincide with that of the subcarrier segment being measured.

91. NBC Dynamic Test Signal. The test signals previously described cannot be used during program transmission. There has been a growing need for a standard signal which could be transmitted during program periods, without interference, to measure and establish levels and measure the system response. Such a signal has been under development and is in experimental operation. It may undergo substantial revision before being accepted as an industry standard and in its present form represents only one possible form of signal.

This standard signal may occupy from three to six lines near the end of the vertical blanking. Three lines are normally transmitted but the number and the exact

location are tentative and subject to additional tests and observations. The lines of the standard test signal are identical in form. The vertical-blanking signal and color-reference-burst signal are assumed to be transmitted normally. The test signal being described is added in each line following the reference burst signal.

With respect to time, following the back porch, there is a bar having an amplitude of 50 units on the IRE scale and a duration of 20 μsec. The amplitude of this bar is precisely adjusted and maintained. Superimposed an dcentered on the bar is 10 μsec of a 3.579-Mc sine wave phased tentatively 180 deg from the reference sub-carrier burst. At the conclusion of the bar a 2-μsec interval occurs at blanking level
FIG. 77. Stair-step signal. (a) CRO wave-form display. (b) Normal signal. (c) Signal after h-p filter.

whereupon another 3.579-Mc sine-wave burst is transmitted, phased for magenta, 60.8 deg, of a duration of 10 μsec. This is followed by 2 μsec of blanking level, whereupon another bar appears at 100 on the IRE scale of a duration of 20 μsec. Centered in this bar in time there is a 10-μsec interval of 3.579-Mc sine wave phased for cyan, 283 deg, the amplitude of which varies between 60 and 100 on the IRE scale. Following this bar the axis returns to the blanking level and the horizontal synchronizing pulse for the next frame appears in conventional manner. The amplitudes of the sine waves span 40 deg on the IRE scale in each case. The experimental standard test signal and the significant phases are illustrated in Fig. 78.

Monochrome Standard Signal. For monochrome transmissions the 3.579-Mc sine waves are removed but the pedestal levels remain. By observing the level of these pedestals at the output of a system, it is possible to determine if amplitude compression exists, and the degree.

Color Standard Signal: For color transmissions the above comments apply in addition to the following. The amplitudes of the three sine-wave signals are the same as the color burst in the video signal. These are also the same as sync amplitude.

Thus sync, burst, and chroma as well as white levels are all established by the standard signal.

By passing the signal through the conventional high-pass filter for this purpose all the low-frequency components are removed and as a result the a-c axis of color burst and the three sine waves of the standard signal are in line. If no differential gain distortion is present in the system these should all have the same amplitudes.

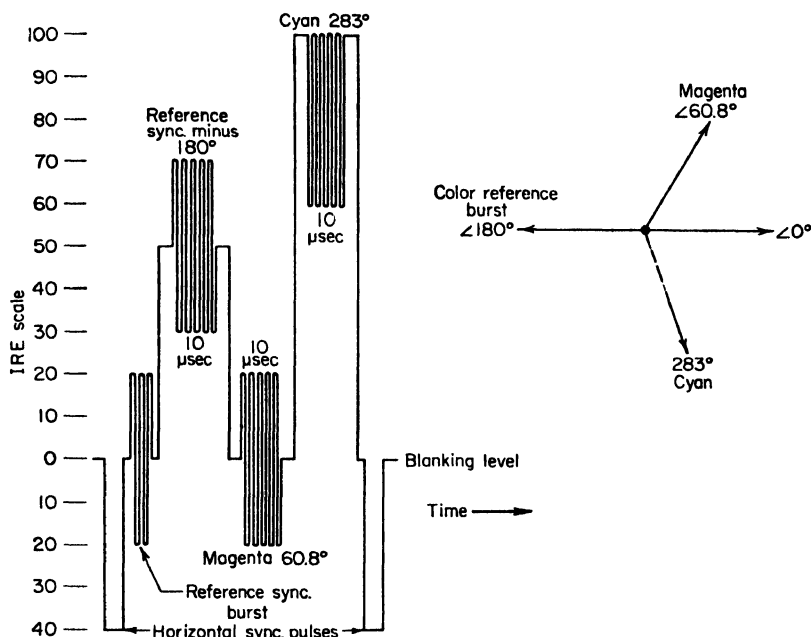
When displayed on a vectorscope a color program combined with the standard signal will contain three dots indicating subcarrier burst minus 180 deg, cyan, and magenta which may be clearly seen. Thus differential phase shift is easily measured


FIG. 78. Single line of NBC experimental standard test signal transmitted during vertical blanking interval, following vertical sync. Three consecutive lines are transmitted.

while the system is in use. The three lines of information provided by the standard signal per field are adequate for a vectorscope presentation.

It is expected that the standard signal will be inserted so that it appears as early in the system as possible. This means the system from camera to receiver may be measured.

It should be pointed out that either adjusting vertical centering in a monitor or receiver or a slight misadjustment of the vertical-hold control will permit the three bars of color on their respective pedestals to appear above the top of the picture. These signals may aid in adjusting a color receiver.

This signal promises to make local and network operations much simpler and more consistent and enable the telephone company to locate circuit faults more easily. Performance characteristics of transmitters may be more accurately determined by its aid.

CHAPTER 23

FACSIMILE

By A. G. Cooley[1]

1. Definitions. For the sake of convenience the following definitions of the terms used in discussions of facsimile are given. The definitions of many more terms will be found in the Institute of Radio Engineers' publications.[2]

Facsimile is the process or the result of the process by which fixed graphic material (subject copy), including pictures or images, is scanned and the information converted into electric signal waves used either locally or remotely to produce in record form a likeness (facsimile) of the subject copy.

Photofacsimile systems reproduce the subject copy on photographic papers or films.

Direct recording produces an image on a record sheet which is visible immediately upon recording, *i.e.*, without photographic developing or processing. Some direct-recording systems are intended only for black-and-white copy such as printed or typed matter, line drawings, etc., rather than photographs or full-tone pictures with areas of varying density. Other types are designed to give a reasonable approximation of photographic quality as in the electrolytic recorders. The end product of the recording process may, by the use of suitable recording material, be a facsimile duplicating master such as a hectograph master, mimeograph stencil, or printing plate.

Elemental area is any segment of a scanning line of the subject copy the dimension of which along the scanning line is exactly equal to the nominal line width. This has sometimes been called the scanning spot, although it is not necessarily the same. The terms "bit" and "bit rate" have also been used. In this discussion "element" and "element rate," respectively, will be used as being more directly applicable.

Picture Frequencies. The frequencies which result solely from scanning subject copy.

Note: This does not include frequencies which are part of a modulated carrier signal.

Base Band. In a carrier (or subcarrier) wire or radio-transmission system, the band of frequencies occupied by the signal before it modulates the carrier (or subcarrier) frequency to form the transmitted line or radio signal.

Note: The signal in the base band is usually distinguished from the line or radio signal by ranging over distinctly lower frequencies, which at the lower end relatively approach or may include d.c. (zero frequency). In the case of a facsimile signal before modulation on a subcarrier, the base band includes d.c.

Scanning. The process of analyzing successively in a predetermined pattern, the densities of the subject copy according to the elements.

2. Basic Principles. In a facsimile system the subject copy for transmission is scanned by a light beam, a line at a time, until the entire copy has been seen by the scanning beam. The transmitted or reflected light beam, modulated by the copy, is optically confined so as to pass on to a phototube at any instant the light from an elemental area, generally one one-hundredth inch square or less. The discrete area is referred to as an elemental area, or element for short. In the modulating system

[1] Times Facsimile Corp.
[2] IRE Standards on Facsimile: Definitions of Terms, 1956, *Proc. IRE*, **44** (6), 776, June, 1956.

of the scanner the light from the elemental areas usually controls the amplitude of the transmitted carrier signal. It is customary to use a carrier signal of such a frequency that each cycle of the signal represents one elemental area.

The amplitude of each carrier cycle represents the intensity of the reflected or transmitted light from the elemental area being seen by the phototube at that time.

The signals are transmitted to the facsimile receiver, which records each elemental area in a light or dark shade in accordance with the shading of the corresponding elemental area of the subject copy. The recording may be done by a photographic
Fig. 1. Schematic of a basic facsimile transmitter.

process or a direct-recording process by means of electric current, heat, impact pressure, etc.

The transmitted signals are reproduced on the record sheet in a position corresponding to that of the transmitted elemental area.

3. Transmitter Components. A facsimile transmitter in an elementary form (Fig. 1) can be considered to be made up of the following basic units:

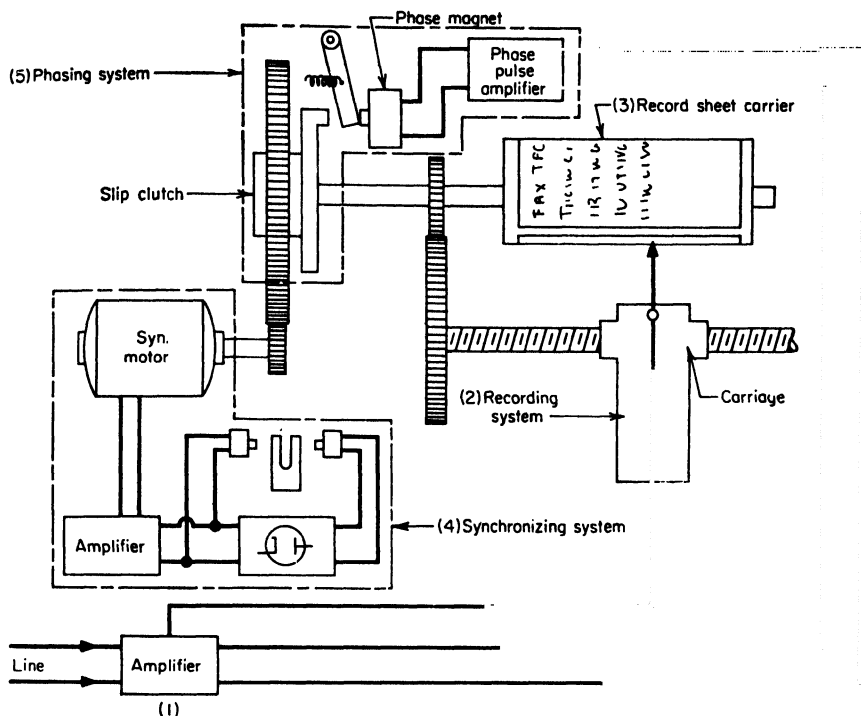
1. A subject copy carrier such as a revolving drum.
2. A synchronizing system for maintaining a constant predetermined scanning speed for synchronizing the machine with the recording speed of the recorder.
3. A scanning system including a light source for producing a beam of light which is reflected from the subject copy onto a light-sensitive device (phototube).
4. A carrier-signal generator.
5. A modulator in which the carrier signal is modulated by the output of the phototube.
6. An amplifier to increase the output of the modulator to produce a signal of sufficient level to transmit over a line or to control a radio transmitter.
7. A phasing pulse generator to indicate the start of a scanning line.


FIG. 2. Schematic of a basic facsimile receiver.

4. Recorder Components. A facsimile receiver in an elementary form (Fig. 2) can be considered to be made up of the following basic units:

1. An amplifier to produce sufficient power under the control of the received signal to operate a recording system.
2. A recording system such as a marking stylus that will burn off the white top coating of a conducting black paper.
3. A record-sheet carrier such as a revolving drum.
4. A synchronizing system for maintaining a constant recording speed corresponding to the scanning speed of the transmitter.
5. A phasing system to place the start of a received scanning line at the left-hand edge of the record sheet.

SUBJECT COPY AND RECORD SHEET CARRIERS

5. Drum-type Carrier. Cylinders or drums are most commonly used as subject-copy carriers. The rotation of the cylinder produces the relative movement in one dimension between the subject copy and the scanning or recording system with good dimensional accuracy and with a simple mechanical system.

Relative movement in the second dimension (normal to the direction of scanning) is produced by moving the scanning or recording system along the axis of the drum or moving the drum along its axis. The first method is illustrated in Fig. 1.

The principle of moving the drum along the axis is shown in Fig. 3. The drum shaft is threaded on one end with the number of threads per inch equal to the required scanning lines per inch. A nut engages the threads and is kept from turning by an extended arm that rides in a track. The nut pushes the drum as the shaft rotates.

Rotational motion is imparted to the drum through the shaft keyway and key attached to the drum.

"Drunken" threads or variations in angular velocity of the shaft will not produce a line-feed pattern or grouping of the recorded lines in the copy. This arrangement permits rigid mounting of the scanning or recording systems; therefore, no flexible connections are required. More space is required for the drum travel than with the moving carriage arrangement of Fig. 1.

Copy-holding Methods. The subject copy is held on the drum with various forms of clamps. One arrangement used extensively employs a "garter spring." The garter spring is rolled along the length of the drum just ahead of the scanned line (Fig. 3).
FIG. 3. Rotational and longitudinal motion imparted to drum through lead screw. Subject copy is fastened to drum by garter spring.

Some machines clamp only the leading edge of the copy and keep the trailing edge against the drum with cowlings or fingers. The copy is sometimes held against the drum with a transparent plastic sheet. There is no noticeable degradation in the recorded copy caused by the light beams passing through the transparent sheet in scanning the subject copy.

One system[1] makes use of centrifugal force to hold the copy against the inside of a transparent drum which revolves at 1,800 rpm. In another arrangement,[2] the copy is pressed face down against the outside of a nonrotating transparent drum. The scanning beams are rotated inside the drum. If two complete beam systems 180 deg apart are used, it is only necessary to wrap the copy halfway around the drum as the second beam system will start the scan of a line just after the first completes a scan.

Another arrangement[3] rolls the subject copy into a cylinder which is supported by an outside wrapper. A rotating mirror rotates the scanning beam inside the cylinder. The exciter lamp and phototube are external to the cylinder (Fig. 4). The diameter of the cylinder is about 1½ in. A similar arrangement is used for recording: the record sheet is rolled into a cylinder and the recording is done with an internal rotating stylus.

When a transparent photographic film is the subject copy, a transparent drum is employed so the scanning beam may be transmitted through the film.

6. Flat-bed Scanning and Recording. The term flat bed is applied to the method wherein the subject-copy and record-sheet carriers feed slowly in one direction while

[1] Cofer, T. F., Design of a Commercial Facsimile System, *Western Union Tech. Rev.*, **8**, 3, 105, July, 1954.

[2] Gillespie, C. N., "Automatic Facsimile Message Scanning System," U.S. Patent 2443953. Artzt, Maurice, Facsimile Transmission and Reception, "Radio Facsimile," Vol. I, p. 152, RCA Institutes Technical Press.

[3] Zabriskie, Douglas M., Ticketfax Transmitters and Recorders, *Western Union Tech. Rev.*, **9** (3), 93, July, 1955.

the scanning or recording across the sheet is accomplished by moving the light beams or recorder elements. The term "flat bed" is a misnomer as applied to some arrangements. The subject copy or the web (a continuous sheet) may be transported through the system by a partial wrap around a feed roll. The scanning or recording may be made across the part in contact with the roll. The record sheet is generally supplied
FIG. 4. Inside scanning system for nonrotating transparent drum. Western Union Ticketfax transmitter.

in the form of a roll or web. Some arrangements pull the web with gripper rollers close to the edge, and in some cases they push the web through the recording system.

SYNCHRONIZING SYSTEMS

The relative movement between the transmitter scanning beam and the subject copy must be synchronized with the relative movement between the recorder element and the record sheet. In a drum system this is accomplished by rotating the two drums at the same speed.

7. Requirements. Exact synchronization of the movement along the line of scanning is most important. Synchronization normal to the line is not so important. When transmitting message copy, a variation of 5 or 10 per cent in scanning normal to the line may not be objectionable.

Not only must synchronization of scanning and recording along the line of scanning be exact on a long-period basis but there must be no short-period variations as may be caused by variations in the angular velocity of the driving motor or nonuniformity in the mechanical coupling between the motor and scanning system. A variation in the mechanical load may reflect back into the motor, causing its angular position to advance or retard.

Short-period variations in synchronism produce a raggedness in the received copy known as "jitter." The effect is minimized if all errors in the system repeat each scan in exactly the same place. Since gear eccentricity is the most common source of jitter, use should be made of repetitive gearing in which each gear makes one or more full revolutions for each scanning cycle.

Photofacsimile recording systems are extremely sensitive to slight speed variations, which show up as density changes in the recorded copy. Density variations which are too small to be detected by sensitive densitometers may be very apparent on visual examination. Such density variations are usually caused by nonuniform velocity in the drive as the gear teeth change their contact point. The transmitter may have such speed variations without having an effect on the recorded copy.

8. Motors. Synchronous motors operating on the power line are frequently used to drive the scanning and recording mechanisms when the transmitter and

receiver are supplied from the same power source or different power sources which are synchronized.

A reluctance type of synchronous motor is an induction motor having a slotted rotor. The induction-motor action serves to start and drive the rotor close to synchronous speed. Slots in the rotor equal to the number of stator poles form a salient-pole rotor which will advance one pole for each pulse of the a-c driving power which pulls the rotor into synchronous speed after starting.

Another type is known as the "hysteresis" motor. Flux from the stator poles magnetizes the rotor with corresponding poles. The rotor is made of a solid steel alloy of the cobalt type and therefore has a strong coercive force that retains the magnetized poles. The rotating field of the stator pulls the rotor with it without slip after synchronous speed is reached.
FIG. 5. Slow-speed 60-cycle synchronous motor. For each cycle of the magnetic field the rotor will advance one tooth.

The slotted-rotor induction motors and hysteresis motors operate at relatively high speeds, that is, 600 to 3,600 rpm if the power-line frequency is 60 cps.

A third type of self-starting power-line-frequency synchronous motor[1] manufactured by General Electric Company is designed for slow speed. Two of the common speeds are 75 and 100 rpm. This motor is a combination induction motor and phonic-wheel motor. The stator is wound as a two-phase induction motor. The rotor is split in the center, with one end magnetized south and the other north by a permanent magnet. Both the rotor and stator are notched to form a large number of salient poles. The line-up of the poles is such that, in maintaining the maximum pull between the rotating field of the stator and the magnetized rotor, the rotor will advance one pole or tooth each time the rotating field passes through one complete cycle. A motor operating on 60 cps will cause a 36-pole rotor to advance $\frac{1}{36}$ revolution for each cycle, or $\frac{60}{36}$ rps. There will be 100 rpm (Fig. 5).

If connected to a low-inertia load, these motors will start in one-half cycle. If the load inertia is high, mechanical decoupling between the load and motor is required. Ordinarily, a high load inertia is needed after starting to smooth out the power pulses in the motor drive.

This low-speed motor requires no more electrical power for starting than for running. The notched-rotor synchronous motor and the hysteresis motor demand starting power many times that of running power. This is no problem when operating from

[1] Staak, J. H., New Inductor Motor Has Low Speed, Self-start and High Torque, *Elec. Mfg.*, **39** (6), 115, June, 1947.

power lines. Facsimile systems intended for operation independently of power-line synchronization make use of a very stable local oscillator to control the frequency of the power applied to the synchronous motor. The motor-drive circuit includes vacuum tubes, gas tubes, or transistors. Rather than supplying motors requiring high starting power through the amplifier circuit, power from the power distribution line is connected to the motor momentarily.

High-frequency Motors. Synchronous motors of the variable-reluctance Lacour or phonic-wheel type manufactured by Times Facsimile Corporation[1] are employed when the frequency of the electrical power supplied to the motor is high compared with the required shaft speed (Fig. 6). These motors can be made to run efficiently on frequencies up to 3,600 cps and will drive light loads on frequencies as high as 6,000 cps. High-frequency operation eliminates or reduces the frequency-dividing requirements between the oscillator and the amplifier. Another advantage is that variations from no load to full load in the mechanical system produce only a very small angular displacement of the rotor, which has a large number of salient poles.

FIG. 6. Two-phase phonic-wheel synchronous motor.

Load Problems. In some cases where there is a problem of supplying sufficient power from the synchronous motor, an auxiliary motor is used to supply slightly more or slightly less than the average mechanical requirements.

The problem of large loads is handled in other systems by controlling a variable-speed motor with a phase-sensing device (Fig. 7). The principle is to generate a frequency directly proportional to the speed of the mechanical system and to match the frequency and phase with those of a stable oscillator.[2] A phase displacement

FIG. 7. Phase-error-sensing system for synchronizing.

between the two will cause the variable-speed motor to advance or retard sufficiently to correct for any phase displacement. Sometimes an eddy-current brake is employed to control the speed.[3] The braking power can be as much as ten times the electrical power applied to the brake. Such arrangements may be classed as servo systems involving error detectors and correctors. They are especially helpful in any system where there is a tendency for the load to reflect back into the motor.

The jitter produced by a load variation reflecting back to the motor is ordinarily a function of the ratio of the number of scanned elemental areas per second divided by the number of power cycles per second. For example, if two receivers operating at the same linear scanning speed in inches per second have a 60-cps motor in one and a 240-cps motor in the other, a load variation in the 240-cps motor set will produce

[1] Synchronous Motor Model MS, 2 Phase, Times Facsimile Corp. Service Bulletin, **9** (6), 33, October–November, 1955.

[2] Turner, F. T., L. G. Pollard, and C. R. Deibert, "Electric Motor Speed Regulation," U.S. Patent 2715202.

[3] Morgan, A. R., and M. Artzt, Color Television Recording, Part III, The Tape Transport Mechanism, *RCA Rev.*, **17** (3), 350, September, 1956.

one-fourth the jitter of the 60-cps set. This rule of thumb, however, does not take into account the motor "stiffness" or the kinetic energy of the rotors. The latter will vary as the square of the speed and is helpful in reducing effects of momentary load variations.

9. Amplifiers. Motor amplifiers, except those used for the phonic-wheel motors, may be of the conventional type using either vacuum or gas tubes in the output stage. Phonic-wheel motors which advance one pole per cycle require pulsating d-c power. The motor efficiency is best when there is no reversal of magnetism in the poles. To obtain this, plate current is passed directly through the motor coils. If the motor has high-impedance windings the required ampere-turns may be obtained with low plate current. To match the high motor impedance with that of the tube, an impedance-matching network is sometimes used.[1]

10. Synchronizing Oscillators. Oscillators for controlling the speed of the synchronous motors driving the facsimile equipment must have an exceptionally high degree of accuracy to prevent skew in the recorded copy. The degree of accuracy depends upon the number of elemental areas in the subject copy and the tolerable skew. News-photo machines transmitting 8- by 10-in. copy and scanning 96 lines per inch will produce satisfactory copy if the oscillators at the transmitter and receiver are operating within 1 part in 100,000 of the assigned frequency. Systems transmitting 12- by 18-in. weather maps require frequency accuracy of 1 part in 300,000. To transmit a full-sized newspaper page at 200 lines per in. the oscillators must operate within one part in 5×10^6 of the specified frequency to keep the skew in the received copy from appearing noticeable.

The frequency accuracy requirement in parts per million (ppm) is determined by

$$A = \frac{\Delta d \times 10^6}{2\Sigma L} \quad \text{ppm}$$

where Δd = tolerable skew in one transmission
ΣL = total length of all scanning lines in one transmission
ΣL is multiplied by 2 because allowance has to be made for the transmitter and receiver drifting in opposite directions from specified frequency.

11. Forks. Bimetal compensated tuning forks[2] operating at frequencies between 1,000 and 2,500 cps are commonly used to synchronize facsimile systems. The major portion of the bimetal or laminated fork is made of a nickel steel having a low temperature coefficient of expansion and a positive temperature coefficient of modulus of elasticity between 0 and +65°C. This is compensated by a lamination of carbon steel having a negative temperature coefficient of modulus of elasticity through that range. The bimetal forks ordinarily do not require temperature control or adjustments over periods of several years.

Specifications for an average bimetal tuning fork to be used in facsimile equipment are:

Stability:

1. ±3 ppm at room ambient temperature (no oven)
2. ±1 ppm after temperature equilibrium is attained ±5°C
3. Short-term drift rate less than 2 ppm per month during first 3 months of operation
4. Long-term drift less than 5 ppm per annum after first 3 months
5. Temperature compensated to less than ±0.2 ppm per °C from +10 to +65°C

Forks requiring a higher degree of stability are available by aging and selection. Stability of 1 part in 15 million is possible if the fork is maintained at a constant temperature and is aged for a year or more.

One type of fork is vacuum-sealed in a stainless-steel tube. The drive and pickup coils are external (Fig. 8). Final factory adjustment is made after the fork holds frequency over a wide temperature range. Service adjustments to take care of aging

[1] Cooley, A. G., "Synchronous Motor Circuit," U.S. Patent 2257158.
[2] "Fork Oscillators," Times Facsimile Corp. Service Bulletin, **10** (1), 3, January–February, 1956.

are made by varying the driving power. A 7:1 change in driving power will effect a frequency change of about 1 part in 20,000.

Tuning forks which are properly balanced will operate in any position with little effect on the frequency. Low-frequency (below 1,000 cps) tuning forks are not ordinarily used because the tines are difficult to balance and, being larger, are more sensitive to the direction of the force of gravity.

Since the frequency is affected by the drive, the output of the driving amplifier must be held constant. This is accomplished by the use of a limiter amplifier ahead of the output stage. Plate voltages are regulated within 2 per cent. It is not necessary to regulate the amplifier heaters (see Fig. 9).

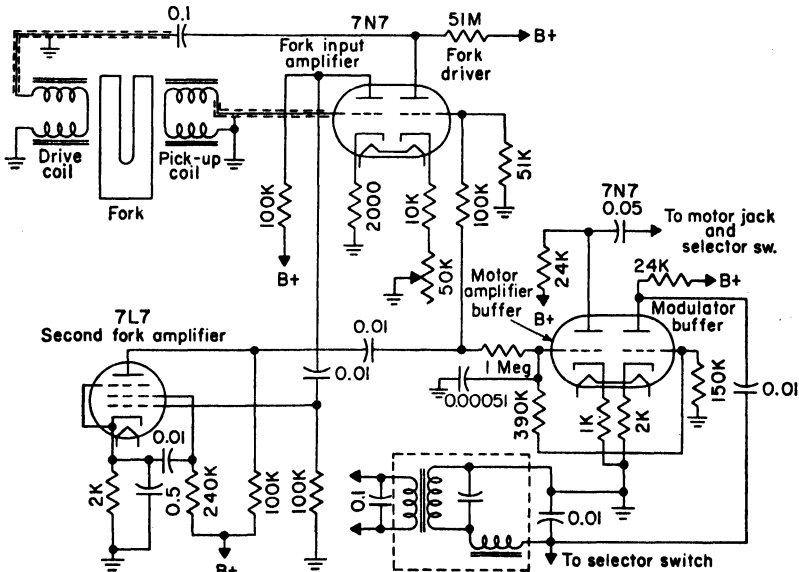
Conventional frequency dividers are used when the fork frequency is a whole multiple of the motor-drive frequency. In facsimile equipment designed to operate at more than one speed, changes of speed may be made by changing the frequency of the power to the synchronous motor. This is accomplished by selecting a fork frequency which can be divided into the proper frequencies to give the required motor speeds. In some cases it is necessary to divide down to a low frequency and multiply up to a higher frequency. An oscillator which will both divide and multiply is shown in Fig. 10.[1] The wave shape across the resonant circuit
FIG. 8. Sealed tuning fork with drive and pickup coils.


FIG. 9. Fork-oscillator unit.

[1] Sulzer, Peter G., Modified Locked-oscillator Frequency Dividers, *Proc. IRE*, **39** (12), 1535, December, 1951.

is approximately sine. If the resonant circuit is tuned close to the desired frequency, the circuit will lock over a fairly wide range of driving voltages. If locking over wide ranges of driving voltage and B plus voltages is desirable, a diode clipper referenced to the oscillator B plus must be used at the input. The oscillator is rich in harmonics, which makes it possible to operate at fractional divisions such as $2\frac{2}{3}$, by locking through control of a harmonic.

To simplify the problem of matching speeds between different systems, it has been suggested to manufacturers of equipment used in international services that the control frequencies be some multiple or submultiple of 300.
FIG. 10. Frequency-divider circuit. Feedback 0.1-μf capacitor is adjusted for output frequency which may be as low as one-fifth or one-sixth of the input.

Phonic-wheel motors can operate at the fork frequencies, thereby eliminating the requirement of frequency dividers. Hysteresis-type synchronous motors are now being manufactured which will operate at 1,000 cps. The shaft speed of these motors is exceptionally high. Muirhead hysteresis motors include a gear reducer in the motor frame.

TRANSMITTER-SCANNER OPTICAL SYSTEMS

12. Flood Projection. The most commonly used optical system for scanning subject copy is shown in Fig. 11. The subject copy is illuminated by a large spot of light. The image of the illuminated area is focused on a plate having an aperture to admit light to a photosensitive device. The light through the aperture represents the reflection from an elemental area.

Flood-projection systems are arranged so the specularly reflected light from a shiny or mirrorlike surface is not directed into the pickup or objective-lens system. The axis of the objective-lens system is usually perpendicular to the subject copy. The illuminating-system axis is usually displaced about 45 deg from the objective-lens axis.

A pair of planoconvex lenses are frequently used in the condensing system. A larger cone of light from the exciter lamp can be obtained with a single spherical-aspherical condensing lens. The aspherical side of the lens is shaped to correct the aberrations of a spherical system. This enables the use of a larger-diameter lens than would be practical with lenses having only spherical surfaces.

If the subject copy has creases or folds, shadow lines will appear in the recorded copy if a single beam of light is used to illuminate the scanned area. The shadow can be reduced by adding a second beam on the opposite side from the first.

Another way of reducing the shadow effect is to use an ellipsoidal mirror which directs the illuminating rays to the scanned area from all sides and at a steep angle (Fig. 12).

13. Spot Projection. A few facsimile systems employ the spot-projection arrangement shown in Fig. 13. The scanning spot does not exceed the size of the elemental
FIG. 11. Flood-projection scanning system.

area on the subject copy. Reflector or lens systems are often employed to aid the pickup of light reflected from the elemental area. Such a system is shielded from ambient light.

The objective lens must be corrected for spherical aberration. In most cases a pair of planoconvex lenses will suffice, but for improved results and elimination of the air space between lens elements it is customary to use a cemented lens having the corrections of a cemented doublet or a Hastings triplet.

Passage of scatter light through the aperture is kept to a minimum by stops in the lens barrel and blackening of the walls.

The aperture may be a square with one side equal to the width of the scanning line times the magnification of the system. If the image of the boundary between a black-and-white area is scanned, the phototube current will gradually change from minimum to maximum as the image of the boundary line crosses the aperture. Therefore, there is no sudden change of phototube
FIG. 12. Flood-projector scanning system with mirror instead of condenser lens.

current during a change from black to white in the copy. The failure to produce a sudden current change is known as *aperture distortion.*[1] In most systems the distortion in the transmitted signal will vary, depending upon the phase relation between the carrier pulse and the timing of the boundary-line passage over the aperture. Although aperture distortion is not an important factor in most systems, it can, as a refinement, be corrected or adjusted in the electric circuits or by changing the size or shape of the aperture. Sometimes the signal is overcorrected in the electric circuits to emphasize the border lines and assist in the transmission of thin lines which are less than the width of an elemental area. This is sometimes referred to as *unsharp masking.*
FIG. 13. Spot-projection scanning system.

Contrast. Scanning contrast of the optical system can be checked by imaging on the aperture a thin black line having a width which will just fill the aperture. The ratio of the line-image phototube current and white current should be at least 1:10, or 20 db.

14. Flying-spot Scanners. The spot-projection system is convenient to use in flat-bed flying-spot scanners. In mechanical systems the spot is swept by a moving mirror or rotating prism along the line to be scanned. In electronic systems operating at very high speeds the spot is formed on the face of a cathode-ray tube and swept across the face with conventional arrangements. It is then focused onto the subject being scanned (Fig. 14). Such a system was used by RCA in the "Ultrafax"[2] equipment, which demonstrated the transmission of 500,000 words per minute.
FIG. 14. Flat-bed flying-spot scanner of electronic type.

The interest in flying-spot scanners is based on the demand for a simple copy-loading system. Interest is centered around the four types shown in Figs. 15 through 18.

The *oscillating-mirror system*[3] is being developed by the Western Union Telegraph

[1] Artzt, Maurice, Facsimile Transmission and Reception, "Radio Facsimile," Vol. I, p. 153, RCA Institutes Technical Press.

[2] Bond, Donald S., and Vernon J. Duke, Ultrafax, *RCA Rev.*, **10** (1) 99, March, 1949.

[3] Buckingham, William D., A Flat-bed Facsimile Telegraph Transmitter, *Western Union Tech. Rev.*, **10** (3), 118, July, 1956.

Company (Fig. 15). It requires but little precision in the manufacture of mechanical parts because all mechanical errors repeat in the same position in each scanning line. The light source is a miniature tungsten-arc lamp developed for facsimile use. The light is emitted from a tungsten ball ten-thousandths of an inch in diameter. The mirror images the point of light on the copy to be scanned. The magnification of the optical system is 1. The mirror is oscillated by a cam which produces a fast return. A speed of 360 scans per minute is no problem. Tests have been made up to 1,800
FIG. 15. Flat-bed flying-spot scanner using oscillating mirror.
FIG. 16. Rotating-mirror type of flat-bed flying-spot scanner.

scans per minute. In the physical equipment the light beams are reflected back and forth between mirrors to reduce the space requirements of the equipment. This arrangement is referred to as "folded optics."

The *rotating-mirror system* of flying-spot scanning is being developed by the Signal Corps Engineering Laboratories and Times Facsimile Corporation (Fig. 16). It offers high optical efficiency and simple rotating mechanical parts. The precision requirements for the optics and mechanics are high.
FIG. 17. Rotating-helix type of flat-bed flying-spot scanner.
FIG. 18. Spiral-aperture system for flat-bed scanner.

Helix-type scanners[1] are manufactured by Alden Electronic and Impulse Recording Equipment Company. The aperture in a flood-projection-type optical system is the intersection of a long slit and a helical slit in a cylinder (see Fig. 17). A strip across the subject copy to be scanned is imaged on the aperture plate with the long

[1] Mathes, R. E., "Facsimile Reproducing Device," U.S. Patent 2167460.

slit. Light passing through the aperture is collected and reflected to a photomultiplier tube. The image on the slit is optically reduced so the physical dimensions of the rotating barrel with the helical slit will not be large. Space is also saved with folded optics.

Instead of the straight slot and helix, a system developed by the Hogan Laboratories, Inc.,[1] employs a slit in the form of a rotating spiral. The intersection of this slit and a long radial slit forms the aperture. In the physical make-up of the equipment, there are several turns of the spiral in the disk. A second revolving single-spiral disk masks off the unwanted spiral slits which are at the intersection with the stationary slit (see Fig. 18). The multiple-turn spiral is used to increase the angle of intersection with the stationary slit, thereby forming an aperture which is close to that of a square (see Fig. 18). Light passing through the aperture combination is directed to a photomultiplier tube. The image on the aperture system is optically reduced so large spiral disks are not required. Folded optics are also used in this arrangement.

LIGHT SOURCES AND TRANSDUCERS

15. Exciter Lamps. In the flood-projection systems low-voltage high-current filament-type lamps, such as those used for automobile headlights, are customary light sources. Short rugged filaments are desired as they do not sag and change position with use. When operated on a.c., the cooling during the zero portion of the cycle is less for heavy filaments than for the lower-current lamps, as shown in Fig. 19.

FIG. 19. A-c hum as a function of lamp current.

Spot-projection systems frequently employ a *crater lamp* of the R1130-B type[2] manufactured by Sylvania Electric Products, Inc. Rather than forming a spot by means of an aperture, the crater itself may be the spot source. While the lamp is designed for recording systems, it is useful as an exciter lamp in many transmitter scanning systems.

The exciter-lamp supply in a direct-recording facsimile system that is intended to record only black-and-white copy may be 60-cycle sine-wave a.c. if a lamp drawing 4 amp or more is used. The effect of cooling on lamps drawing lower currents may be reduced by supplying 60-cycle square-wave power. An approximation of square-wave power is developed in a saturable-core-type voltage regulator operating at its maximum rated voltage.[3] With this arrangement, the system may be used for transmitting photographs when operating with a 2-amp lamp.

The cooling effects of the lamp filament can be reduced by employing frequencies higher than 60 cps. The power supply in the military FX-1 and TXC-1 equipment supplies 1,800-cps power to the exciter lamp. The 1,800-cps signal is derived from the carrier frequency oscillator. The output of the power amplifier is accurately regulated by the system shown in Fig. 20.

An 1,800-cps signal is applied to a grid of a variable-gain tube. The output stage of the amplifier system drives a transformer having a 6-volt tap for the exciter lamp. This transformer has an additional output winding which feeds a rectifier. The rectified voltage

[1] Hogan, John V. L., and George M. Stamps, New Continuous-feed Facsimile Scanner, *Elec. Eng.*, **73** (7), 615, July, 1954.

[2] "Sylvania Glow Modulator Tube," Times Facsimile Corp. Service Bulletin, **8** (6), 29, July, 1954.

[3] Curtis, R. C., and S. J. Martin, "Exciter Lamp Operation," U.S. Patent 2496273.

is balanced against a reference voltage established by a 5651 reference-voltage tube. Any changes in balance are amplified and fed back to control one of the grids of the variable-gain input tube. If the output of the amplifier varies, the d.c. sent back to the input tube will change the gain and reestablish the lamp voltage to the correct value.

The control circuit consists of a rectifier which applies a negative voltage to the cathode of a multigrid tube. A constant voltage drop is inserted in the negative supply to the cathode by means of a 5651 regulator tube. One grid of the tube is connected to the supply ahead of the regulator tube so it is sensitive to voltage variations in the supply. Variations are therefore amplified and appear across the output resistor between plate and ground.

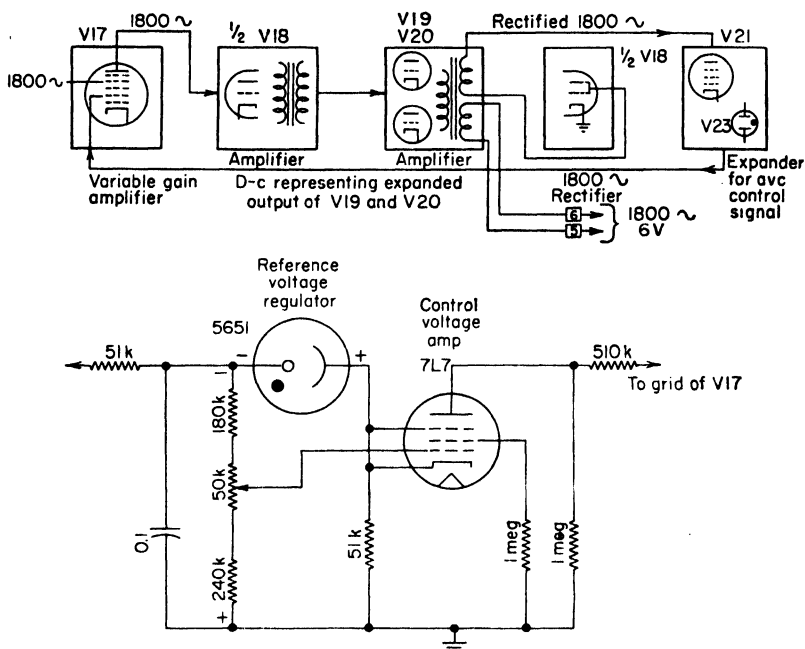
This system will hold the lamp-voltage variations to 1 per cent when the supply voltage to the power pack rapidly varies between 90 and 130 volts.


FIG. 20. (*Above*) Regulated 1,800-cycle exciter-lamp supply. (*Below*) Control-voltage amplifier.

Glow-modulator tubes used as exciter lamps are sometimes supplied with power at carrier frequency. Regulated d-c power is supplied to the crater lamp in other systems.

In the Telognosis system[1] for transmitting X-ray films of wide density range, the intensity of the light from a glow-modulator tube is controlled by feedback to produce an output signal of proper contrast. When scanning dense portions of the film the glow lamp current and intensity are increased above average, and they are decreased when scanning thin portions of the film, thus reducing the contrast range.

In transceivers, the crater lamp may serve as an exciter lamp while transmitting or a recorder lamp when recording.

16. Phototubes are used for interpreting the light from the elemental area in terms of electric current. Both gas and vacuum types are employed. The vacuum type

[1] McConnell, K. R., "The Transmission of X-ray Films by Facsimile," AIEE conference paper, June 1953 (available through Times Facsimile Corp.).

has a higher degree of stability but requires 10 to 20 db more amplification. The gas tube is generally unsatisfactory when a frequency response higher than 5,000 cps is required. When exposed to modulated light the sensitivity drops about 8 per cent between 1,000 and 5,000 cps.

The color response of the phototube is determined by the cathode material. This is in the form of a thin film on a metal support. A film of Co-O-Ag has its greatest sensitivity in the red end of the spectrum. Cathodes of this type are designated S-1. An S-4 coating of Cs-Sb has a more uniform response to the visual rays but its greatest sensitivity is in the blue region. Although facsimile recordings are usually black and white or intermediate shades, the subject copy is frequently in colors such as road maps. The S-4 coating is the more satisfactory for differentiating between colors, even though this is not apparent from Fig. 21.

Fig. 21. Spectral response of S-1 and S-4 coatings.

Since the S-4 coating is sensitive in the blue region, it is very susceptible to fluctuations in the exciter-lamp intensity if a filament-type lamp is used. Thus, any variations in filament temperature near the upper limit of its rating are exaggerated when phototubes having the S-4 coating are used.

Multiplier-type phototubes are used when the light available from the elemental area is so low that the output from other types of phototubes is not sufficient to override microphonics and amplifier-tube emission noise. It is also helpful to have the high picture-frequency level of the multiplier tube to control modulating circuits.

Use of the photomultiplier tube eliminates the need for voltage amplifiers. The photomultiplier lacks the stability of a simple one-anode phototube and is very sensitive to variations in the dynode voltage.

Phototube sensitivity varies over a wide range. A phototube rated for 60 μa per lumen actually may have a sensitivity in the range of 40 to 90. This factor must be taken into account in designing amplifying systems. Furthermore, the sensitivity of the cathode is not always uniform over the entire area.

The required sensitivity of the phototube will depend upon the available light from the elemental area and the limitations of signal-to-noise ratio. The available light is so low in some flying-spot types of scanners that photomultiplier tubes must be used.

Other light-sensitive devices such as phototransistors, photovoltaic cells, and photoconductors[1] are not used in facsimile systems because of speed of response or temperature effects on sensitivity.

Microphonics and flexible leads are the two outstanding problems with optical systems mounted on a moving carriage such as that shown in Fig. 1. If a high-impedance phototube is used, it is often helpful to employ an amplifier having a low output impedance mounted adjacent to the phototube. A cascode stage offers certain advantages as a coupling element in meeting this requirement. Analysis of this amplifier shows that the wire joining the lower and upper stages operates at an impedance in the order of 1,000 ohms. This makes it convenient to separate the two halves—the lower half located close to the phototube and the upper half located at a distance. The circuit shown in Fig. 22 has a gain of about 800. The equivalent input noise is 4 μv. This is about one-fourth of the noise voltage generated by the
[1] Smollet, M., and J. A. Jenkins, The Lead Sulfide Photo-conductive Cell, *Electronic Eng.*, **28** (343), 373, September, 1956.
FIG. 22. Cascode coupling for phototube output.

2.2-megohm phototube load resistor. The equivalent input noise can be reduced to half by operating the filaments on d.c. The cascode depends on relatively high transconductance in the lower stage and high amplification factor in the upper stage. This makes it convenient to separate the two triodes, the lower (V_1) located close to the phototube and the upper (V_2) located at a distance. The circuit in Fig. 22 has a gain of about 800 from V_1 through V_3.

CARRIER-SIGNAL GENERATORS

17. Frequency. The lowest carrier-signal frequency that should be used is determined by the maximum number of elemental areas to be scanned per second and is limited by the maximum usable frequency band width of the communication channel. If single, lower, side-band transmission is to be employed, the carrier frequency can be about 40 per cent higher in the same available band width than it can for double side band.

Sharp cutoff filters for attenuating the upper side bands introduce a signal distortion so there must be a vestigial side band between the carrier frequency and the cutoff frequency of the filters or communication channel. In a communication channel having a cutoff frequency of 2,700 cps it is customary to employ a carrier of 2,400 cps. The general practice is to keep the carrier at least 10 per cent below the channel cutoff frequency.

The carrier frequency is sometimes set close to the cutoff frequency of the communication channel without any attempt to remove the upper side bands at the transmitter. These side bands are attenuated in the communication channel.

18. Synchronous Carriers. When transmitting to photorecorders which print the individual elemental areas that are distinguishable from each other, the carrier-signal generators are locked in with the synchronizing system. Unless a synchronous relation is attained, the elemental areas will print in a random pattern and produce a very noticeable effect. The effect is reduced or eliminated if the received signal is demodulated and smoothed out.

Lockin of the carrier with the synchronizing system is generally effected by controlling the synchronous motor from the same oscillator which supplies the carrier. The problem is minimized if the motor-drive frequency and carrier frequency are the same.

MODULATORS

19. Balanced Modulator. Modulators of the balanced type are normally used so as to reduce to a minimum the picture frequencies in the output of the modulator. Double balanced modulators such as the lattice type (ring type) prevent such frequencies from transmitting through a following amplifier. If the picture frequencies are present to a significant degree in the modulation products they cause severe distortion through heterodyne action with the carrier and the side bands. If a balanced modulator is not used, these frequencies can be reduced by a filter or the use of an

amplifier which discriminates against low frequencies, in some cases by the use of small coupling capacitors between stages.

If the picture frequencies (which might be described as "keying thump") are transmitted into the line, there is a good possibility that some of them will be attenuated less than the carrier with its modulation products. This will produce an etching effect in the recorded copy.
FIG. 23. Multiplier phototube and modulator.

A balanced modulator controlled by a photomultiplier tube is shown in one form by Fig. 23. This consists of a multiplier phototube, a pair of cathode followers, and a silicon-diode ring modulator. The phototube dynode-voltage divider is powered by a regulated negative voltage supply to stabilize the current amplification. The dynode-voltage divider is terminated in a stiff voltage source of about plus 25 volts. The two cathode-follower grids are also connected to this point—one through the phototube load resistor and the other through a potentiometer system for adjustment of a modulator balance. The two cathode followers form a balanced system which minimizes drifting of the modulator balance with changes in cathode temperature.[1] The phototube load resistor is not operated as part of the dynode bleeder. When light causes current to flow to the anode, its potential falls below that of dynode No. 9. This makes the sensitivity of the phototube fall off with increasing light. The voltage across the anode load resistor is approximately the log of the light intensity. Bifilar winding of the split coils of the modulator transformers assures balance of the leakage fluxes. The capacitor across the driver transformer should tune the transformer to resonance at the carrier frequency. The *RC* network damps ringing of the output transformer and partially rounds off the square wave which the modulator diodes deliver.

The cathode-follower grids are operated above ground so that large cathode resistors can be used to degenerate drifting further.

20. Phototube Modulator. A balanced modulator[2] which is used extensively is composed of a simple bridge circuit with the phototube in one arm. Light on the tube will balance or unbalance the bridge depending upon the modulation requirements.

[1] Hogan, J. V. L., and Frank A. Hester, "A Facsimile System Having Response Linear with Optical Density," A.I.E.E. conference paper, January, 1952 (available through Hogan Laboratories, Inc., New York, N.Y.).

[2] "The Photocell Bridge Circuit in TFC Transmitters," Times Facsimile Corp. Service Bulletin, **5** (1), 9, January–February, 1951. Shonnard, J. R., Facsimile Modulator Tube, *Electronics*, **21** (6), 82, June, 1948.

A simple, stable, balanced modulator is shown in Fig. 24. A carrier generator feeds the bridge approximately 1 volt peak (E). Dark balance occurs when $R_1 = R_2$ and $C_1 = C_2$. As light is admitted to the phototube, photoemission produces current through the load resistor R_L. The direction is controlled by the instantaneous phase of the carrier potential and the magnitude is proportional to the light flux. The resultant output of the bridge is a modulated carrier with upper and lower side bands. The picture-frequency band is eliminated when the phototube elements produce equal and opposite emission so that no d.c. appears in the load resistor R_L.
FIG. 24. Bridge modulator using double phototube.
FIG. 25. Bridge modulator using RCA 5652 phototube.

The dark resistance of phototubes is very high, causing their circuits to be sensitive to leakage due to humidity. High-impedance wiring external to the tube also contributes to instability. To minimize these problems a special phototube was designed by RCA. This tube, designated 5652, is shown in the simplified circuit in Fig. 25.

The conventional anode is unnecessary because the cathode surface collects as well as emits electrons depending on the polarity of the applied signal. The active electrodes act alternatively as cathodes or anodes provided both surfaces are illuminated. Except for the external load all high-impedance wiring, including the neutralizing capacitor C_2, is incorporated within the tube envelope to provide maximum stability. Variation in photosensitivity of the individual cathodes is compensated by proper division of the light striking the two plates.

In *light-modulation* systems, the scanning beam is interrupted at carrier frequency. The interruptions may be effected by a light chopper or the source of light may be from a glow-modulator tube such as a Sylvania R1130B supplied with power at carrier frequency. The interrupter may be in the form of a slotted revolving disk or the vibrating shutter of a galvanometer. The beam is modulated by the light reflected from the elemental area. The picture frequencies must be removed.

SIGNAL AMPLIFIERS

21. Requirements. The recorder of a facsimile system is a form of recording oscillograph and thus shows any signal deterioration even though only a momentary transient is involved. A-c signal amplifiers must therefore be substantially free from microphonics, noise, hum, tendency for parasitics, etc. D-c amplifiers must be free of drift.

22. Gain Requirements. The maximum signal available from a phototube system in the average facsimile transmitter not employing a photomultiplier tube varies from 0.0002 to 0.1 volt. The amplifier output requirement is generally 0 dbm into 600 ohms.

A facsimile receiver supplied by a signal from a phone circuit will, in most cases, have an input level of −20 dbm (0.078 volt) to −10 dbm (0.25 volt). In most facsimile systems the power required to operate the recording element is less than 20 watts.

If the system is used for phototransmission, there must not be any sudden changes in gain which amount to ¼ db but long gradual level changes of even 1 db may not be noticed in the received copy. In black-and-white systems sudden changes of

1 db can be tolerated. These parameters apply to the combined amplifier and power-supply design.

Expanders and compressors are used in phototransmitters and receivers to effect tone correction. The expanders and compressors are designed to avoid any abrupt change in the slope of the curve showing gain vs. input-signal level. A circuit that will give the required correction for recording on Eastman Kodak transmission film, type C, is shown in Fig. 26. The minimum lamp current is 1.5 ma and the maximum 40 ma.

Amplifiers for phototransmitters are normally corrected to produce an output voltage which is linear with the density of the subject copy.

23. Frequency Requirements. In a double-side-band photofacsimile system the band-width requirement is usually in the range of one-half to one and a half times the carrier frequency. Allowing for Kendall effect this assumes the system is designed
FIG. 26. Compandor circuit for recorder density correction.

to take advantage of the maximum usable keying frequency for the available carrier frequency.

In SSB systems the band-width requirement is generally from one-half the carrier frequency to the highest vestigial side-band frequency of importance (usually about 1.1 to 1.2 times the carrier frequency).

In the transmitter amplifier it is good practice to keep the frequency response over the band width employed within ±2 db of the gain at the carrier frequency. Satisfactory results are frequently obtained even if the gain drops off 6 db at the lower end, provided this drop is gradual. Such tolerances, however, do not apply to the receiver amplifier, if the facsimile signal into the receiver is a combination of audio-frequency shift (AFS) and a.m. This is frequently the case with signals delivered from a discriminator at the output of a radio receiver. In this case the signal contrast will be changed if the amplifier is not flat.

24. Phase Shift. The effects of phase shift in the amplifiers are usually not noticed in the received copy unless some type of filter is used to limit the amplifier band width. In these cases the phase shift must be linear with frequency to the closest practicable degree as any delay distortion in the outputs of the amplifiers will add directly to the delay distortions in the line. The total delay distortion for photofacsimile transmission of high quality should not exceed ±½ elemental area.

Some amplifiers are designed to invert the sense of the signal amplitude with respect to black or white. This is usually done by combining the signal from the phototube amplifier with another signal of opposite phase. The second signal will balance out a strong white signal from the phototube amplifier. In this type of signal inverter, the phase shift becomes very important. Phase shift may be purposely introduced to control the contrast by establishing the amplitude of the minimum signal at null. It is important that the phase shift remain constant in these systems since even a small drift with time or temperature would greatly affect the null amplitude and therefore the signal contrast.

25. Noise. It is generally considered that the peak noise in the system should be at least 10 db below the weakest signal which is to be recorded in a photofacsimile system. Many systems employ a 20-db contrast range in signal between black and white. This means the noise peaks should be at least 30 db below the maximum signal level. In black-and-white systems there is usually no objection to having the peak noise equal to the minimum transmitted signal unless the noise is of such a nature that peaks are very frequent. Good results are generally obtained even if the peak noise is above the minimum signal, and message copy is often readable with the usual size of type even when noise peaks greatly exceed the maximum signal.

Bias systems in amplifiers which operate class A present no problem. However, in an amplifier which does not maintain constant plate current the cathode bias resistors must not be by-passed with capacitors. Biasing capacitors cause a lag in the biasing voltage with respect to signal-level variations. Resistors in screen-grid circuits must not be by-passed if the average plate current is not constant.

26. Power Supplies. To prevent amplifier-gain fluctuations which may be caused by power-line variations, it is common to employ voltage-regulated power supplies. The combination of the amplifier and power supply is generally such that the output signal will not vary by more than $\pm\frac{1}{4}$ db when the power voltage is changed from 100 to 130 volts.[1] If the current drain on the power supply varies with the signal level, the time constant of the power supply often will give trouble by causing a change in gain unless the regulation is very good.

PHASING SYSTEMS

At the beginning of a transmission it is necessary to transmit a pulse indicating the start of a scanning line. This pulse is used to center the recorded image on the recording medium. The pulse may be a short break in maximum signal or it may be a short pulse of a maximum signal.

27. Pulse-generating Methods. Some systems transmit only a single phasing pulse at the beginning of a transmission. Others repeat the pulse for several seconds—in some cases up to a minute if operation is over a radio circuit. Transmitters are often equipped with timing devices to control the number of pulses transmitted prior to the start of copy transmission.

For generating the phasing signal the scanning beam in some systems either will scan white for the greater part of the scanning-line cycle and then a short black segment, or will scan black the greater part of the cycle, then a short white segment. In one system the scanning beam is blocked off during the greater part of the cycle and then permitted to strike a short white segment to produce the pulse.[2] This is done to eliminate false signals caused by scanning specks of dirt.

In some arrangements the phasing pulse is generated by a momentary closure of a switch or a sliding contact.

28. Recorder Phasing. Phasing is defined as the adjustment of the picture position along the recording line. In a broader sense phasing is the centering of the recorded image on the recording medium. In practice, the phasing pulse received from the transmitter determines the starting position of the recorded line. If the phasing is correct the recording of the line will start at the edge of the record sheet.

The phasing system shown in Fig. 2 is sometimes referred to as *stop-start* phasing. The receiver drum is stopped by the armature of the phase magnet engaging the clutch. A phasing pulse releases the clutch to start the recording at the edge of the record sheet. This system is commonly used where speeds are not great and the synchronous motor has sufficient power to operate against the stalled clutch.

The clutch friction must be great enough to pick up the mechanical load with very little slippage after it is released by the phasing pulse. The clutch-face materials

[1] "Voltage Regulator Circuit," Times Facsimile Corp. Service Bulletin, **10** (1), 1, January–February, 1956.

[2] Cooley, A. G., "Phasing Arrangement for Telefacsimile Machines," U.S. Patent 2246721.

are selected for a high ratio of static friction to sliding friction to prevent slippage during recording.

Some systems arrange to lock up the phase magnet immediately after the clutch is released for the first time. In other systems the phasing pulses are received over a period of several seconds so that the receiving operator can determine that phasing is correct. This is helpful when operating over radio circuits subject to random noise bursts which may cause false phasing unless there are such provisions for checking.

The phasing pulse is ordinarily demodulated and passed through a low-pass filter. This protects the receiver against false phasing on very short noise bursts.

In the Western Union Desk Fax[1] facsimile system which normally operates over physical circuits of short distances (8 miles or less), the phasing is accomplished by the transmission of a d-c pulse. This pulse is controlled by a commutator in the customer's transceiver. At the main office the pulse phases both the receiver and the transmitter with the customer's machine.

Some receivers driven by self-starting synchronous motors are brought into phase position by momentarily interrupting the power to the synchronous motor and permitting it to slip synchronism by one or more poles during each break.[2] The power interruption is repeated several times until the recording mechanism is in correct phase position. The indication is sometimes accomplished by having the receiver system develop a phasing pulse which is compared with the incoming phasing pulse. When the two are coincident, the system is in phase.

Instead of slipping the synchronous motor to bring the mechanism into phase, the motor is sometimes supplied with power of a frequency slightly higher or slightly lower than the synchronous frequency.[3] The receiver will then run slower or faster until the pulses are coincident.

If the speed of scanning is slow, considerable time is required to bring about phasing coincidence. If the recording speed is high, coincidence can normally be accomplished within 2 or 3 sec.

The coincidence system of phasing has the advantage over the stop-start system in that there is very little change of load on the synchronous motor during the phasing period.

Most of the advantages of both the stop-start phasing system and the *coincident phasing* system are realized in the *phase-corrector* phasing system. In such an arrangement the phasing error of the receiver is indicated upon the receipt of the first phasing pulse. A correcting mechanism operates until the indicated error is zero. In one form the correction is accomplished by rotating the frame of the synchronous motor.

DIRECT RECORDERS

Direct recorders approximating the schematic form shown in Fig. 1 are in wide use (over 30,000 in the United States in 1957). In addition to communications, similar facsimile principles are used for copying letters or forms and for producing duplicating masters.

29. Record Materials. The *dry electrosensitive* type of direct recorder uses a *record sheet* of the Timefax NDA[4] or Teledeltos[5] type. The surface of the sheet is a light gray, and although the resistance is high, current will pass through it to the lower-resistance undercoating or backing. Considerable heat develops under the recording stylus when a voltage is applied. This is due to the I^2R losses in the surface coating. The passage of signaling current causes disintegration of the top coating, exposing

[4] Times Facsimile Corp.

[5] Western Union Telegraph Co.

the black undercoating and thereby leaving a black mark. Writing speeds of over 1,000 in. per sec have been attained.

Teledeltos paper consists of a conducting carbon paper with a white pigment coating. Timefax paper has a coating of low-resistance carbon adhering to a white bond sheet. On top of the low-resistance layer is a high-resistance layer. This is coated with a modified zinc oxide pigment which is semiconducting. Variations of both types of recording papers are available which permit reproductions to be made by hectograph and litho-offset printing methods.

30. Recording Power Requirements. The amount of power required to mark direct-recording papers depends upon many factors, including the thickness and electrical characteristics of the electrosensitive surface coating, the stylus-to-paper speed, the stylus size and pressure, the frequency of the recording current, and the polarity when recording with d.c. A light pressure is desirable, and tungsten is preferred for the stylus tip to minimize wear, although steel is sometimes used. The
Fig. 27. Band drive for web-type continuous recorder.

power required for marking at different paper writing speeds varies directly as the speed. The voltage required increases only slightly with increase in speed. If d.c. is used with positive polarity on the stylus, about 7 watts is required for a maximum-density recording over a given area, with line spacing of 1⁄100 in., a paper writing speed of 50 in. per sec, and a stylus pressure of 7 g. The printing voltage for Timefax is about 225 volts for maximum density at 20 in. per sec and about 150 volts for Teledeltos. The maximum density is about 1.6 as measured on a Photovolt densitometer. This reading takes into account the surface characteristics of the paper and may differ from the readings obtained with glossy black, so far as the apparent density or "blackness" on visual inspection is concerned.

31. Web-type Recording. The trend in direct recorders is toward the continuous-web type as they do not require reloading after each transmission and will operate without attention. Many of the dry electrosensitive types are used in meteorological services, and there is a need for them in message-communications operations. The styluses are moved across the width of the web by a continuous band driven at synchronous speed. Three or four styluses are attached to the band so that, when one recording line is completed, the following stylus will start the next line.

The Western Union system drives the band and maintains its phase position by sprocket holes in the band.[1] The Times Facsimile system employs a nonsynchronous drive to one of the wheels on which the band is mounted (Fig. 27). The band is prevented from running above synchronous speed by engagement of lugs on the band with a synchronously driven arm rotating concentrically with one of the wheels.[2]

[1] Hallden, F. G., Three Stylus Facsimile Recorder for Concentrator Service, *Western Union Tech. Rev.*, **4**, 16, January, 1950.

[2] Cooley, A. G., and P. L. Grafstein, "A New 18-inch Wide Continuous Web Facsimile Recorder," Conference Paper CP55-774, 1955 (available through Times Facsimile Corp.). Cooley, A. G., and P. L. Grafstein, "Design Factors in Continuous Facsimile Recorders," A.I.E.E. conference paper, January, 1954 (available through Times Facsimile Corp.).

The Western Union system has the styluses attached rigidly to the band. The web along the line of scanning has a resilient backing. The backing for the web in the Times machine is rigid but the styluses are resiliently mounted on the band.

32. Pressure-sensitive Recorders. These are used for printing mailing-address labels.[1] Complete four-line labels having 25 characters per line are printed at the rate of 200 per minute. The marking is done by pressure applied to a wax-carbon paper. This requires two webs, the record sheet and the carbon paper.

A single-sheet pressure-sensitive arrangement has proved out in prototype machines and can be expected to reach commercial production. The paper is made up of a
FIG. 28. Pressure-sensitive recorder, helix and bar type.

sheet of bond paper on which is a coating of black ink or dye. The dark coating is masked with a thin layer of wax or metallic soap. The metallic soap is preferable since the melting point is above 200°F. The masking layer contains air bubbles which produce a white appearance. Pressure from the marking stylus compresses the wax or metallic soap and makes it transparent, thus exposing the dark undercoating.

33. Helix and Bar Recorders. In this system (Fig. 28), sometimes called *lawn-mower* recording, the pressure-sensitive sheet is passed between a rotating helix and a bar.[2] When the bar is magnetically moved toward the helix a mark will be made on the record sheet along the line of intersection of the helix blade and the bar. The helix is driven at synchronous speed so the intersection point makes one complete sweep across the record sheet during each scanning cycle.

Magnetically driven recorders of the helix and bar type are limited in printing speed by the mass of the bar. Recorders having a bar length of 8 in. have found only limited use. The recorders for printing mailing labels referred to above have a

[1] "Tape Facsimile Addressing Machines," Times Facsimile Corp. Service Bulletin, 7 (9), 39, October, 1953.

[2] Young, C. J., "Picture Receiving Apparatus," U.S. Patent 1848862 (reissued as Re. 20152).

bar that is about 3/16 in. long and prints only one line of type. Four recording heads are used to print the four lines of the labels. Each head has a printing capacity of 7,000 elemental areas per second (keying frequency of 3,500 cps).

The U.S. Army Signal Engineering Laboratories have had success with a direct-recording system employing three magnetically operated styluses carried on a band in a continuous-web recorder. The unique magnetic system is shown in Fig. 29. This arrangement reduces the travel requirements of the armature to the amount the pressure-sensitive record sheet compresses under the pressure of the stylus.
Fig. 29. Magnetically driven stylus for recording on pressure-sensitive record sheet.

34. Ink Recorders. Ink is used as the marking medium in a Siemens-Hell-Fax recorder of the drum type manufactured in Germany. The magnetically actuated stylus is a disk 1/8 in. in diameter and is referred to as the "writing wheel." The writing wheel is inked from a driven rubber ring, the surface of which is inked by an inking roller.

Ink has been used in helix and bar systems. The ink was applied to the helix through a transfer roll. A few of these machines are still in service, although the
Fig. 30. Helix and bar type of electrolytic recorder.

Hell-Schreiber tape of facsimile equipment of this type was used quite extensively at one time in radio press services. Ninety-eight elements were required to make up one character. Only seven elements or bits are required for one character in a printing telegraph system; so the tape facsimile could not compete in this service. The tape facsimile is, however, used as a stand-by for operation when radio conditions are too poor for printing telegraphy.

35. Electrolytic recorders[1] are being used in news-photo services for newspapers and television stations. Some electrolytic recorders are used for recording weather maps and they are being developed for message-communications service. The translucent recording paper may be used as a master in light-sensitive duplicating machines such as Ozalid or Bruning.

Electrolytic recorders are generally of the helix and bar type shown in Fig. 30. The record sheet is moistened with an electrolyte. Current passes through the sheet at the crossover point of the bar and helix. In some systems the electrolyte colors upon the passage of current.[2] Paper developed by Hogan Laboratories gives a black recording by dissolving iron from the steel marking anode with an alkaline substance formed in the paper by the passage of current. The paper may contain sodium nitrate, pyrocatechin and water, for example, and the iron reacts with the pyrocatechin in the presence of the alkali to form a dark substance (color lake) at the recording point.

PHOTORECORDERS

Photofacsimile recorders find their greatest use in news-photo services. Radiophoto services that handle picture traffic use the photorecorders for black-and-white as well as continuous-tone subjects. Some use is being made of photofacsimile for transmitting newspaper copy for proofreading and for publication from the received film. Photofacsimile recordings have been made at speeds up to a million words a minute over very-wide-band channels by the Ultrafax® system. The Ultrafax recorder is similar to the scanner shown in Fig. 14 except for the photomultiplier tube. Negative film is transported in the place of the subject copy.

36. Glow-lamp Recording. Either film or a bromide paper is exposed in the photo-facsimile recorders by a light which varies in intensity at the carrier or modulation frequency. Most of the recorders manufactured today use the glow-modulator tube type R1130-B. The light output is proportional to the current through the lamp and the voltage across the lamp remains fairly constant even though the current may vary over a range of 50 to 1. A cross section of the glow-modulator tube R1130-B is shown in Fig. 31. The characteristics are shown by Fig. 32. The light forms along the walls of the crater in the zirconium cathode when a positive potential is applied to the anode. Looking into the crater, the light appears doughnut-shaped.

FIG. 31. Glow-tube modulator, Sylvania R1130-B.

A positive potential exists along the axis of the crater and the walls are at negative potential. This causes electrons emitted from the walls to be accelerated laterally to the center. They continue toward the opposite wall but are repelled by the potential minimum there. This oscillation occurs many times before the electrons are eventually drawn out of the crater to the anode, thereby providing an extra long path for the electrons.

The ions and the electrons carry the discharge current through the tube while the excited molecules of cathode vapor emit light when they return to their normal state. In effect, a vaporizing of the cathode material is the source of light. Light produced by the glow of the fill gas is negligible. The modulation characteristics are therefore a function not of the ionization and deionization time of the gas but of

[1] Hogan, J. V. L., H. C. Ressler, and W. H. Tribble, "Electrolytic Recording," U.S. Patent 2358839. Hogan, J. V. L., J. W. Smith, and A. H. Mones, "Electrolytic Recording for Facsimile," A.I.E.E. conference paper, February, 1955 (available through Hogan Laboratories, Inc., New York, N.Y.).

[2] U.S. Patents 2339267 and 2358839.

the rate of heating and cooling of the cathode vapor discharge. The frequency response is dependent upon the gas pressure which affects the cooling rate. The total light output goes down at a given current as the pressure of the gas filling increases because of the increased rate of heat conduction away from the crater. For modulating frequencies in the range of 50 kc, a gas pressure of 25 mm is used. The current may be as high as 150 ma for periods of several minutes. During the first 5 or 10 sec of operation of a high-pressure lamp, there is an increase in light output.
FIG. 32. Characteristics of the R1130-B glow tube.

Mica disks positioned above the opening in the anode help to collect material from the cathode which would otherwise be deposited on the window of the envelope, thereby cutting down the light.

A typical optical system for a glow-modulator tube is shown in Fig. 33. The objective lens focuses the image of the aperture on the record sheet. The highest optical efficiency is obtained when the aperture plate and field lens are close to the envelope of the glow tube. Under these conditions, however, the objective lens will image the lamp crater as well as the aperture on the record sheet, thus producing an undesirable spot for recording.
FIG. 33. Recorder optical system using glow-tube modulator.

One purpose of the field lens is to focus the image of the crater on the front surface of the objective lens. If this could be fully accomplished, the image of the aperture on the record sheet would not be blurred with an unwanted image of the crater. Because of the depth of the crater, a sharp image cannot be placed on the surface of the objective lens unless the spacing between the crater and aperture is great. This is because the anterior depth of focus of the objective lens is large. A diffuser between the crater and aperture will prevent the objective lens from seeing the crater, but this advantage is obtained at the cost of light efficiency, generally a 2 to 1 reduction.

If maximum optical efficiency is required, the crater can be focused on the record sheet with a single lens, omitting the aperture and field lens. With this arrangement, the image is round and not clearly defined. The recorded elemental areas are then not of uniform density, and they build up into recorded lines which vary in density across the lines.

It is common to use objective lenses having focal lengths of ½ to 1 in. The optical efficiency can be improved a small amount by using shorter-focal-length lenses, but

the posterior depth of focus is so short that any minor bulges in the record sheet or an irregularity of the record-sheet carrier causes an out-of-focus effect on the recorded copy. Devices for clamping the record sheet on the carrier (drum) protrude beyond the surface and determine the shortest focal length which may be used without risking mechanical interference between lens tube and record-sheet clamps.

37. Films. Eastman Kodak Transmission films type A and type C are commonly used in news-photo work. The *H* and *D* curves are shown in Fig. 34. Both type A and C can be developed, fixed, and dried rapidly. For high-speed recording Contrast Process Ortho[1] has proved satisfactory.

Enlarging paper such as Kodabromide F1[1] is suitable as the record sheet when positive prints are required.

FIG. 34. *H* and *D* curves for Eastman Kodak types A and C films.

38. Positive and Negative Recording. This technique can be accomplished on the same machine without reversing the scanning direction with respect to the line advance by placing the film on the drum with the emulsion side down so the image will appear in the same left-to-right sense as camera negatives. Placing the emulsion side down also has a handling advantage in that fingerprints on the back of the film do not appear in the finished negative. The glow-modulator tubes produce sufficient light to expose the emulsion properly after passing through the antihalation backing.

If a *mechanical system* such as shown in Fig. 2 is used to move the recorder optical system along the length of the drum, careful consideration must be given to the design and construction. Irregularities produce an underlap or overlap of the recorded elemental areas. Irregular underlap and overlap produce undesirable patterns. This is called *grouping* when the variations develop patterns the full length of the scanning lines. If the recording is at the rate of 100 lines per inch, a variation in underlap or overlap of 0.0005 in. is usually acceptable, depending somewhat upon the sharpness of the recording spot and the rate of variation.

Very small variations in the lead-screw pitch will produce grouping unless the number of lead-screw threads per unit length is equal to the number of recording lines per unit length. Grouping is also caused by a cyclical variation of the lead screw along its axis as it rotates. To keep this type of camming to a minimum, the lead screw is usually end-loaded against a cone bearing or a single-ball thrust bearing. A slight amount of eccentricity of the lead-screw gears will cause grouping. In most cases the eccentricity of the pitch line must be under 0.001 in. The carriage must fit firmly to the ways so the optical system cannot vibrate in any direction. The carriage must slide without any variation in load that will reflect back to the gears and motor.

TELEPHONE CIRCUITS FOR FACSIMILE TRANSMISSION[2]

There are now over 114,000 miles of telephone circuits in the United States which are being used for facsimile. Telephone circuits that are suitable for voice communications are not necessarily satisfactory for facsimile. The problems of wire-line transmission must be considered.

39. Requirements. Facsimile transmission over telephone circuits does not place severe demands on the communication channel if the copy to be transmitted is essentially black and white, in which legibility is the primary criterion and appearance
[1] Eastman Kodak Co.
[2] By A. C. Mitchell, Times Facsimile Corporation.

only secondary. The requirements for quality of transmission are much greater than in the case of voice communications if consideration must be given to many degrees of middle tones and complete freedom from visible effects of level changes, noise, frequency patterns, transients, echoes, and delay distortion. This second and more demanding class of material always requires photographic or high-quality electrolytic processes to produce the received copy while the first makes use of conventional direct-recording methods.

For example, the relation between facsimile machine characteristics and transmission qualities of telephone lines can be determined as follows.

Assume the requirement is to transmit 8- by 10-in. subject copy at a resolution of 100 lines per inch along the scanning line and normal to the scanning line, and that the transmission time is to be 8 min. The required element rate (per second) would be

$$\frac{8 \times 10 \times 100 \times 100}{8 \times 60} = 1{,}665 \text{ elements per sec}$$

To transmit this material in 8 min, however, allowance has to be made for a small portion of the scanning operation used for blanking, or phasing, for instance, the clamp bar of a drum-type scanner. If we assume 8 per cent for this we get 1,665 + 135 = 1,800 elements per second as the rate needed to transmit the copy in 8 min.

The effective band for facsimile transmission would then be 900 cycles, and, to avoid overlap in the voice-frequency portions of the telephone lines between the base-band frequencies (0 to 900 cps) and the lower side band of a carrier system, the carrier might be placed at 1,800 cps if double-side-band transmission is involved. The two side bands would then extend from 900 to 2,700 cycles.

This band could be accommodated by almost any type of telephone-message circuit for widely different limiting lengths as far as frequency band width is concerned. (One exception would be an "E.B." split channel.) This does not, however, necessarily mean that an ordinary telephone-message circuit will be satisfactory in every respect. The reasons for this are explained below under the several types of unwanted phenomena.

40. Envelope-delay Distortion. This phenomenon can be ignored in voice transmission but is of great importance in facsimile. Envelope-delay distortion is a measure of the difference in propagation time of the frequencies making up the envelope of a transmitted signal element.

For high-quality transmission of original photographs, experience has shown that the delay distortion should not exceed ±½ elementary area (element). This limit expressed in microseconds would be inversely proportional to the element rate employed in transmission. For example, at 1,800 elements per second, used in the example above, the time of half an element would be

$$t = \frac{1{,}000{,}000}{2 \times 1{,}800} = 280\ \mu\text{sec}$$

The limit for envelope-delay distortion over the band of modulation frequencies from the carrier minus 900 cps to the carrier plus 900 cps should not exceed ±280 μsec for the most exacting type of facsimile transmission with photographic-recording processes. If instead of 1,800 elements the rate was 18,000, the permissible delay distortion would be only ±28 μsec.

In the case of black-and-white typed or printed material where legibility is the most important consideration and with existing direct-recording processes, ±500 μsec would be tolerable at an element rate of 1,800.

As for the severity of this trouble for the same lengths of circuits, telephone systems making use of carrier techniques usually have much less delay distortion than those which do not use such techniques. The delay distortion within the usual facsimile band of 900 to 2,700 cps for 100 miles of certain types of voice-frequency loaded-cable system might be as much as twenty times greater than one 100-mile *K*-carrier link. In carrier-frequency systems the distortion is mainly in the terminal equipments

so that it is roughly proportional to the number of links of carrier channel rather than the length of the circuit. In voice-frequency loaded-cable systems nearly all the distortion is in the loaded cable itself and is closely proportional to the length. See curves of Fig. 35.

Correction for delay distortion is usually made by installing the necessary number of sections and characteristics of passive-delay equalizer networks. Variable active-delay equalizers are also available.[1] In any case the delay equalizing is done by adding more delay at the frequencies having small value of delay to make the delay more nearly the same for all picture frequencies.
Fig. 35. Envelope delay of four representative telephone circuits.

41. Attenuation Distortion. Facsimile circuits should be held to a flat net loss-frequency characteristic between 1,000 and 2,800 cps within considerably narrower limits than are required for satisfactory telephone transmission. Facsimile introduces a further complication in that the carrier frequency usually employed is 1,800 cps or higher, whereas all telephone-circuit layouts are based on 1,000-cps attenuation and loss data. In circuits especially designed for facsimile transmission, special attenuation equalizers are installed in various sections of the circuit depending to some extent on its length.

The most serious attenuation problem is frequently in the local exchange area when the local channels sometimes are fairly long nonloaded cables of No. 19, 22, 24, or smaller gages where the attenuation at a picture carrier of, say, 2,400 cps may be many times as much as at 1,000 cps (see Table 1).

Another peculiarity of exchange-area cables is that, for telephone service, impedance irregularities in such cables usually are of little importance and therefore are prevalent. Two such irregularities in a loaded cable will react on each other to produce wiggles in the attenuation-frequency characteristic which, while not in themselves important, may produce associated peaks and valleys in the delay-frequency characteristic the results of which may be visible on photographically processed recordings.

[1] Cannon, W. D., "Delay Distortion Correction," AIEE Transactions Paper No. 56-107, January, 1956.

42. Level Changes. The most frequent cause of complaint in facsimile, particularly photofacsimile, comes under this heading. Here again the sensitivity of this type of transmission to changes in level is much greater than that of telephone service, say, about ten times as great. The requirement of limiting sudden level changes to something less than ¼ db necessitates special facilities for photofacsimile channels.

Continuous but small (fractions of a decibel) changes in level are caused by hunting of the dynamic regulators which are used in the newer types of telephone systems. These level changes can be detected in areas of what should be uniform middle tones in reception by photographic processes, and the effect has been appropriately called *uneasy background.* They are of no consequence in telephone transmission but in a circuit specially engineered for facsimile transmission the telephone company might want to apply in some line sections pilot-tone level-compensator equipment designed

Table 1. Approximate Maximum Lengths of Nonloaded, Nonrepeatered Exchange Area Cables with an Attenuation Loss of 12 Db at 1,000 Cps

Gage	Type	Capacitance, μf per mile	Max length, miles	2,400-cps loss increase over 1,000 cps, db
22	BSA and CSA	0.082	8.1	7.5
24	ASM and CSA	0.072	5.5	6.1
24	DSM	0.084	5.2	6.3
26	ST and AST	0.069	4.5	6.5
26	BST	0.079	4.2	6.4

to eliminate this effect. This would remove not only the uneasiness of the background but also frequency patterns (a special kind of recurring level changes discussed in the next section) coming from power or telephone circuits, and all other level changes of as much as ±5 db, when such a change occurs within the compensated section of line. The system[1] utilizes a pilot frequency just outside of and above the frequency band used by facsimile machines of a maximum element rate of about 2,400 and will therefore compensate for level changes during the transmission. While the system has a fast enough response to compensate for a 180-cps frequency pattern (the third harmonic of 60-cps power interference) this is not fast enough to compensate for short hits (defined below) but it will have a limiting effect on long hits.

Sudden and transient changes in received signal level are called *hits.* These may vary from a small portion of a scanning line to several scanning lines depending on the duration of the hit and the linear speed of recording.

43. Noise and Frequency Pattern Interference. Noise in a telephone-message communication channel becomes either random specks and streaks, or more or less regular frequency patterns, in the facsimile record copy. The specks or short streaks (random noise) may be caused by vacuum-tube noise, atmospheric static, ignition noises, cross modulation or cross talk, etc., and the frequency pattern by intermodulation of extraneous frequencies such as those of power circuits, or testing or signaling frequencies used in adjacent telephone circuits with frequencies in the facsimile transmission ranges.

In the case of random noise the rms level at the input to the facsimile receiver should be at least 35 to 40 db below the level of the maximum picture carrier when high-grade photofacsimile with photographically processed recordings is involved.

In black-and-white transmissions when copy appearance is not important but perfect legibility is demanded, the noise could be many decibels higher than this, depending, for instance, on the size of the lettering of the copy. For 12-point boldface characters the rms noise should be not less than 10 db below the signal.

[1] Jones, T. A., and W. A. Phelps, "A Level Compensator for Telephotograph Systems," AIEE Technical Paper No. 53-297, June, 1953.

Frequency pattern interference is important mainly in high-grade photofacsimile in which the copy may be so sensitive to this type of interference that it may be discerned even when it is 55 db or more below the maximum signal level.

44. Echo. The effect of echo on the appearance of a facsimile recording when the echo has a short delay is practically undistinguishable from the effects of delay distortion, although the causes are different. An echo may be caused by two approximately equal and sufficiently large impedance irregularities or one very large and one small one in the transmission path, separated from each other by a finite amount of delay, or it may be caused by having the main transmission path from the transmitter to receiver paralleled in part or entirely by a second path of a different amount of delay. In either case two (or more) sets of the same transmitted data are recorded with differences in time. Echo is a frequent and important cause of unsatisfactory
FIG. 36. Typical alternate facsimile full-period station arrangement.

copy in the case of high-grade phototransmission and may also, when severe, interfere with legibility of black-and-white transmissions.

45. Circuits Engineered for Facsimile Service. All common telephone-message circuits are "two-wire" circuits in at least some links connecting the two telephone sets. Many circuits are completely "two-wire" for the entire length. This means that the same transmission path is used for both directions of transmission. Such a circuit tends to have more noise, echo, and cross talk and to be much more vulnerable than a completely "four-wire" circuit where two separate paths, to a high degree independent of each other, are provided for each direction of transmission.

For more reliable, and generally more satisfactory facsimile transmission, the telephone circuit should be made effectively a four-wire circuit during the transmission of the facsimile signal. Other special conditioning is often required, such as delay and attenuation equalization, application of echo suppressors, level compensators, and maintenance within more stringent tolerances than those required for telephone service. For high-grade photofacsimile transmission such an upgrading of an ordinary telephone-message channel in most cases is a practical necessity and for black-and-white transmission it will frequently be found desirable.

46. Terminating Arrangements for Facsimile Service. There is a considerable variety of facsimile-service terminating arrangements, depending to some extent on local conditions and requirements at the place where the facsimile machines are installed.

In the case of a network with a number of different sending or receiving points, it is usually advantageous for both the facsimile-service user and the communications company responsible for maintaining the network for the terminating arrangements

at all points to be as nearly as practicable the same. An example of a terminating arrangement with no special features is shown in Fig. 36.

RADIO FACSIMILE

News photos and weather maps make up the greater part of facsimile radio traffic. There is some traffic in the form of financial reports and documents that cannot be readily transmitted by code or printing telegraphy. The problem of errors in these two systems is developing a trend toward facsimile for message traffic.

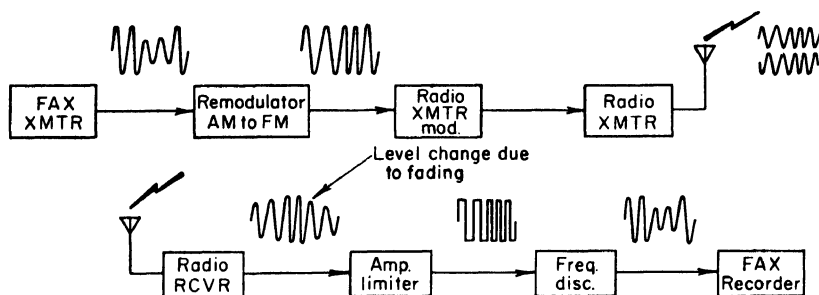
47. Radio-transmission Difficulties. Radio circuits making use of sky-wave transmission paths require the use of auxiliary equipment if the degradations are to be kept to a minimum. The basic problem of fading and noise is met by converting the a-m signal of the facsimile transmitter to a frequency shift signal of 800 cps total shift. This signal may be transmitted as an audio-frequency shift signal (AFS) or as a shift of the r-f carrier itself (RFS).


FIG. 37. Audio-frequency shift system using a voice-frequency radio circuit.

48. Audio-frequency Shift (AFS).[1] When a double-side-band a-m radio circuit or a narrow-band f-m circuit is available, AFS (formerly referred to as subcarrier frequency modulation) is most convenient. Both the transmitting and receiving stations are relatively easy to operate. The transmitting and receiving r-f oscillators do not require a high degree of stability. With respect to distance of transmission and freedom from multipath effects and noise, the AFS system is somewhat inferior to RFS transmission described later.

A remodulator is needed at the transmitter to convert the a-m facsimile signal into an AFS signal. A discriminator is required at the receiver to convert the AFS signal from the radio receiver into an a-m signal for the facsimile receiver.

The block diagram in Fig. 37 shows typical transmitting and receiving stations using AFS.

SSB a-m radio circuits are used with the same arrangement of the auxiliary equipment. The degradation caused by multipath phenomena is less than with the double-side-band a.m. or narrow-band f.m. If the carrier is entirely suppressed, the signal is the same as with the FS circuit.

The *remodulator* first demodulates the a-m carrier from the facsimile transmitter to obtain the base band. This signal may control the frequency of one oscillator in a beat-frequency oscillator (BFO) so the beat frequency at the output swings between 1,500 and 2,300 cps. In another system, the demodulated signal controls the pulse-repetition rate of a single-shot multivibrator. A third system which is simple and stable in operation employs an *RC* oscillator whose frequency is controlled by the demodulated signal.

This form of remodulator has an audio *RC* phase-shift oscillator which is more stable than

[1] Mathes, R. E., and J. N. Whitaker, Radio Facsimile by Sub-carrier Frequency Modulation, *RCA Rev.*, **4** (2), 131, October, 1939.

the BFO. The output frequency of the oscillator is varied by a tube in one of the legs of the frequency-determining *RC* network. Rectified signals from the facsimile transmitter are fed to this tube, which acts as a variable resistor to change the period of oscillation. The maximum input signal will produce the 1,500-cps output frequency (Fig. 38).

The *discriminator* units are composed of an amplifier, a limiter, and a frequency discriminator. The amplifier builds up the weakest workable signal to a level sufficient to reach the saturation point in the limiter. All signals above this level will be converted into square waves of constant amplitude. The output of the limiter passes through a frequency discriminator, the simplest type of which is a low-pass filter which passes signals in the 1,500-cps range with much less attenuation than the 2,300-cps signals. The contrast range of the output signal is generally adjustable to meet the requirements of the different types of facsimile receivers. The output signal of this discriminator still contains the a-f shift in addition to the amplitude modulation. Since most facsimile receivers are sensitive only to amplitude, it is usually not necessary to remove the frequency-shift component.
Fig. 38. Simplified schematic of remodulator.

Most other types of frequency discriminators demodulate the square-wave signal to the base band. This d-c signal modulates an a-f carrier to produce an amplitude-modulated carrier signal of fixed frequency. Examples of this type of frequency discriminator are: balanced phase-shift discriminator (as used in f-m broadcasting), frequency counter, single-shot multivibrator, etc. The output of the low-pass-filter frequency discriminator may be rectified to obtain the base band.

The amplitude of the input signal may vary over a range of 40 db or more without affecting the level of the output. Noise below the signal level will be lost in the square-wave envelope. Out-of-phase noise will put a reversal in the normal signal envelope and cause an unwanted marking on the recorded copy when the resultant signal drops below the clipping point.

49. Radio-frequency Shift (RFS). Facsimile signals can be transmitted over a regular c-w radio transmitter which is equipped for frequency-shift modulation. This system is generally used for permanent radio-facsimile circuits. The RFS system is superior in overcoming the effect of multipath signals and noise. Only a very narrow r-f band width is required.

Multipath radio signals, noise, and interference cause degradation of the received copy; so a radio frequency should be selected which minimizes these conditions.

It is customary to arrange a simple switching system so the radio transmitter can be quickly switched to either facsimile or teletype. The facsimile-transmission range is about the same as for teletype or c.w., unless some degradation can be tolerated; in that case, the workable transmission range for facsimile is greater.

The block diagram (Fig. 39) shows a transmitting and receiving station for an RFS radio circuit.

The auxiliary equipment required at the transmitting station is a demodulator to convert the facsimile signal into a varying d-c voltage for the frequency-shift exciter unit or keyer. The varying d-c voltage shifts the frequency of the radio transmitter in accordance with the amplitude of the d-c signal. The oscillators used at both the transmitting and receiving stations must be very stable.

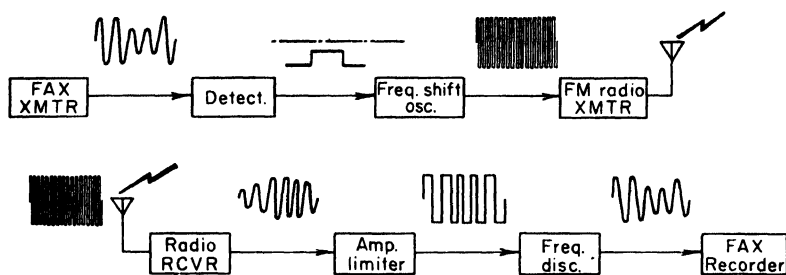
The output of the radio receiver is an audio tone varying in frequency (AFS) in accordance with the frequency shift (RFS) of the radio carrier. The audio tone is developed as a beat frequency between the radio carrier and a stable r-f oscillator feeding the input of the radio receiver. On very stable radio receivers the BFO may be used instead of a stable r-f oscillator. This a-f shift tone is fed into a discriminator to convert it to an a-m signal before it is applied to the facsimile receiver. The discriminator eliminates the effects of signal fading and reduces the effects of interference and noise.


FIG. 39. General features of frequency-shift system.

FACSIMILE-MACHINE CHARACTERISTICS[1]

50. Compatibility. In order that facsimile equipment may be compatible, certain operating characteristics must be common to the transmitting and receiving equipments. Either the equipments must be synchronized to a common reference such as the power-line frequency, or synchronization must be maintained by using high-stability frequency standards at the transmitter and receiver. The degree of synchronization required will depend upon the amount of skew which is acceptable per copy. This requirement may vary from about 20 ppm for systems which have a relatively short total length of scanning line per copy to 0.2 ppm for systems which have a long total scanning line per copy.

If the *indexes of cooperation*[2] are not the same, the received copy will be stretched or compressed. Since it is only the aspect ratio of the received copy which is affected, the latitude permitted will depend upon the subject copy. Unless the difference in index is very great, typed or printed copy will be legible, but a photograph may be unacceptable. A difference in index of cooperation of as much as 10 per cent can often be tolerated.

For drum-type receivers the ratio of drum length to drum diameter (*drum factor*) must be at least as large as that of the transmitter to ensure that the end of the copy will not be cut off.

To obtain proper receiver phasing it must be designed to respond appropriately to the particular type of phasing signals sent out by the transmitter which is to operate it. Most facsimile systems use a series of pulses at the beginning of a transmission to modulate the carrier in the same manner as the picture signals. The

[1] By A. C. Mitchell, Times Facsimile Corp.

[2] (CCIR) The product of the scanning-drum diameter and the number of scanning lines per inch. IRE index = π times CCIR index.

pulses are usually shorter than 5 per cent of the total scanning-line length and are placed at the edge of the copy.

If control signals are used for automatic operation of the receiver it must be sensitive to the particular kinds of signals sent out by the transmitter. For use on circuits which may change the absolute frequency of the signal or the type of modulation, the control signals should modulate the carrier in the same manner as the picture signals.

For recorders which reproduce on an opaque record sheet, the same direction of scanning (normal or reverse) must be used at both ends. The receiver must also be capable of accepting the type of transmission (white transmission or black transmission) being used.

The receiver must be designed to operate on the type of modulation (amplitude or frequency shift) to be used and must have the proper contrast or frequency-shift limits. For good gray-scale reproduction the linearity of the signal amplitude or frequency with copy density must be known. In most systems designed for gray-scale reproduction the relation of signal voltage or frequency with copy density is approximately linear.

51. Compatibility Parameters. The operating characteristics of a facsimile system which determine the compatibility of the transmitters and receivers are listed below:

1. Stroke speeds (lines scanned or recorded per minute).
2. Direction of scan.
3. Starting operations if automatic starting and phasing are used; phasing operations if manual starting is used.
4. Index of cooperation. Wide tolerances are generally permissible for message or weather-map copy.

Table 2. Characteristics of Representative Facsimile Systems

	Copy size transmitted, in.	Drum diam, in.	Scanning lines per in.	Index of cooperation		Scans per min

B. Transmission of meteorological maps and large documents	18 × 12	6.0	96	576	1,810	60	Armed Forces, Weather Bureau, and commercial airlines networks
	18 × 22	6.0	96	576	1,810	60 or 120	Canadian weather network
C. Transmission of business documents	8 × 13 or cont.	2.75	96	264	829	180 or 360	Bell system
	8 × 10	2.63	100	263	825	90, 180, or 360	Western Union
D. Special services.	In this category are systems designed to transmit special kinds and formats of subject copy such as telegrams, tickets, and X-ray films. Western Union has six different facsimile systems for public-service telegraph service with differing drum diameters, scanning lines per inch, and indexes of cooperation. It also has a system for transmitting tickets for space reservations, and for small documents such as brokers' orders. Times Facsimile supplies a facsimile system for transmitting 14- × 17-in. X-ray films at a drum speed of 180 rpm and an index of 264						

52. Facsimile-systems Standards. The International Telegraph Consultative Committee (CCIT) has set up the following specifications for facsimile machines as standards to be used in international communications:

For Photographs:
- Cylinder circumference ($D \times \pi$) .... 8.66 in.
- Min useful circumference .... 8.00 in.
- Max skew .... 0.15 in.
- Useful cylinder length .... 11.81 in.
- Max picture size .... 8.07 × 11.65 in.
- Drum factor .... 2.5 min
- Line advance (scanning density) .... 96 and 127 lines per in.
- Indexes of cooperation .... 264 and 350, respectively (830 and 1,100 IRE)
- Stroke speed (rpm for drums) .... 90 and 60, respectively, and multiples and submultiples

For meteorological charts and large documents:
- Index of cooperation (proposed) 576
- Drum speed (recommended) .... 60 rpm

Proposed for business documents:
- Index of cooperation 264
- Drum diam* .... 2.6 2.95 in.
- Min usable drum length of transmitters .... 11.8 in.
- Drum speeds of 90, 120, 150, 180, 240, and 360 rpm have been proposed

* U.S. State Department proposes standard of 2.75 in.

CHAPTER 24

CODE TRANSMISSION AND RECEPTION

By John B. Moore[1]

1. Basic Considerations. The transmission of information in coded form, rather than by normal voice communication or the written word, is accomplished by the use of so-called "signals" of one form or another. This may be the beating of drums, the use of flags, smoke signals, lanterns, flashing lights, or suitable variation or interruption of an electric current or of an electromagnetic wave. The nature of the information to be transmitted and the capabilities or limitations of the method and facilities available for accomplishing such transmission and reception determine the type of code and its detailed construction.

Suitable coding not only puts information into a form that can be transmitted by available means but it also can be employed in various ways to abbreviate a message or to provide secrecy.

Telecommunication over radio circuits generally must employ some form of coding. Voice communication may be considered as being basically a case of direct reproduction that does not involve any coding of the original intelligence (sampling and pulse coding methods are not considered here). Other forms of intelligence, however, require a coding scheme that will make possible the transmission of the desired information over the type of physical facilities, equipment, and circuit that are to be used.

CODES

Most codes, employed for signaling over wire or radio circuits, are basically of the so-called binary or two-condition type; these two conditions being designated by such terms as *mark-space, on-off, positive-negative, high-low, upper-lower*. Three-condition codes are used on submarine cables, while certain other systems utilize what may be considered *four-condition signaling*. In any such code, a code combination consists of alternate short or long periods of time during each of which only one of the two or more possible conditions is established.

A different type of coding is obtained by the simultaneous transmission, through separate electrical paths over the circuit, of two or more discrete frequencies or tones, each code character consisting of a different combination of one, two, or more of the possible number of frequencies (see Chap. 27).

2. Specific Applications. A full understanding of the fundamental role of coding, in the present-day telecommunications art, requires at least a listing of the various types of service that are based on suitable coding of the electrical signal.

Telegraphy. Codes, such as those shown in Figs. 1 and 2, assign a separate code combination to each letter, character, special function, or arbitrary instruction to be transmitted. Such codes, for radio telegraphy (RT), generally are of the so-called binary or two-condition type.

Switching. Remote or selective control of functions and of communications circuits or routings generally is effected by use of telegraph-type binary codes or of simultaneous multifrequency codes.[5*]

Telemetering. Where measurements of physical quantities are to be automatically transmitted to a distant point, it generally is necessary to convert the relative or

FIG. 1. International Morse code teleprinter codes and typical character assignments.

numerical values of such measurements into a suitably coded form for electrical transmission over a wire or radio circuit, the appropriate type of code being dependent upon information requirements and upon the type of communication channel.

Pulse Modulation. This is basically a binary or two-condition type of coding, in which the original intelligence is sampled at suitably frequent intervals and then is converted into pulses which are so modulated, positioned in time, or coded, as to make possible their reconversion into the original form of the intelligence being transmitted.

Facsimile. The electrical transmission of black-and-white copy and of photographs containing all shades of gray ranging from black to white involves scanning and conversion processes that may be considered a form of coding.

Television. The control of scanning, synchronizing, color selection, etc., necessarily is based on the use of a standard coded signal, the resultant television signal itself being a coded form of the total intelligence being transmitted.

TELEGRAPH CODES

The following treatment is limited essentially to those codes authorized by the international Telegraph Regulations, Paris, 1949,[1] for use over international wire-line and radio circuits. These are so-called binary or two-condition codes, in which the time duration of any marking or spacing interval is a multiple of the shortest or unit interval or unit element (sometimes referred to as a Baudel). Descriptions of other codes, which are of specialized types or which enjoy less widespread use today, can be found in the literature.[2,3]

3. Morse Code. This type of code, one example of which is shown in Fig. 1, consists of dots, dashes, and spaces. The dot is the shortest, or unit, element. A space between dots and/or dashes is equal in length to a dot. A dash is equal in length to three dots. A space between letters or characters is equal in length to three dots, and a space between words to seven dots. (When transmission is by perforated tape, the space between two letters is equal to one "center hole" and the space between two words is equal to three "center holes.")

NOTE: The term "dot," as used here, denotes a mark (M) element of unit length. It should not be confused with the term "dot-cycle," which denotes a mark unit element followed by a space (S) unit element.

The international Morse code, specified in the Telegraph Regulations,[1] is shown in full in Fig. 1. Accented letters peculiar to certain languages other than English, shown in a separate block on the code chart, are used only between offices, stations, or ships of such countries as permit their use. Nationals of countries using non-English syllabaries or alphabets, such as the Japanese and Russian, must spell out the sounds of their own words in one of the languages using the English alphabet. This sometimes requires the use of arbitrary equivalents.

The American Morse code, used chiefly on domestic telegraph services within the United States, differs from the international Morse code in the code combinations assigned to certain letters and to the numerals, and in the use of one lengthened space within the internal structure of a few of these code combinations.

Japan, Russia, and other countries that have their own national syllabaries and alphabets—differing radically from the English alphabet—employ special forms of the Morse code[4] for working within their own countries and territories and to their ships.

4. Morse Cable Code. This differs from the international Morse code, of Fig. 1, in employing equal-length pulses of three polarities—positive, negative, and neutral—to represent a dot, a dash, or a space between letters, respectively. Therefore, it is considerably faster than the dot-dash-space form of the two-condition Morse code. However, the limitations of radio reception, and of most RT transmitters prior to the advent of modern methods of frequency-shift keying, prevented the use of such a three-condition code for radio telegraphy.

To make available the advantages of this equal-element type of cable code, in RT operations, the British Higgitt system employs a so-called two-condition cable code

in which a Morse dot is represented by a M-to-S transition, a Morse dash by a S-to-M transition, and a space between letters by the absence of a transition in the radio signal. The code can be used only in a synchronous system, such as a time-division multiplex (TDM) system, especially designed to function in accordance with precise

FIG. 2. Printer-key arrangements and codes.

timing and other requirements imposed by the code and its proper interpretation by the receiving terminal equipment.

5. Teleprinter Codes. These are distinguished by the feature that, unlike the Morse code, each combination in a given code is of the same length as measured in unit elements or in milliseconds of time duration. Typical examples of the teleprinter codes employed over radio circuits are the five-unit Baudot code and the

"protected" seven-unit constant-ratio code[6] shown in Fig. 2. Both are shown in their basic form as used in synchronous systems where the transmitting and the distant receiving machines (or their electronic equivalents) run continuously and are automatically maintained in synchronism in speed and phase. For nonsynchronous or so-called start/stop operation, where the distributor mechanism of the receiving machine must be started and stopped for each code combination transmitted, each basic combination shown in the chart of Fig. 2 must be preceded by a start (space) signal of unit-interval duration and must be followed by a stop (mark) signal which, in different designs of system, may have a duration of 1.0 or 1.42 or 1.5 unit elements. Thus, a 5-unit start/stop code becomes actually a 7.0- or 7.42- or 7.5-unit code. Any other basic teleprinter code, such as the 6-unit or 7-unit or 8-unit, may similarly have added to it the start and stop intervals required to adapt it for start/stop operation.

6. Baudot Nonprotected. This equal-length teleprinter code, in its widely used five-unit form, is given in Fig. 2. (Start and stop intervals for start/stop operation are not shown.) All combinations are of the same length or time duration, each consisting of five unit elements. By assigning to each unit element either M (0) or S (−) status, there is obtainable a total of 32 combinations. Typical assignments to letters, machine functions, and other characters are shown in Fig. 2, where the letters assignments designate the lower-case position or shift of the receiving printer, and figures assignments designate the upper-case position or shift. A six-unit code, of this type, provides a total of 64 combinations, examples of its application being in Teletypesetter equipment and in the Japanese domestic teleprinter network.

This is called a "nonprotected" code because any mutilation of the signal which changes a mark to a space, or vice versa, results in a different code combination and thus causes an error in the received message.

7. Constant-ratio Protected.[6] This equal-length teleprinter code, shown in its presently used seven-unit form in Fig. 2, is so constructed that each combination consists of 3 M and 4 S unit elements, giving a constant M/S ratio of 3:4. The total number of such combinations is 35. Three combinations, as indicated in the chart of Fig. 2, are assigned to special functions associated with a particular type of system in which this code is used for RT services. An eight-unit code of this type provides 70 protected combinations.

This code provides a high degree of protection against errors caused by mutilated signals, since any change from the correct 3:4 ratio of M to S elements results in an invalid combination that can be detected and registered as such at the receiving office. In the case of weak signals severely affected by noise and fading, it is possible that one unit element may be changed from M to S and another from S to M within one code combination. Such a compensating double mutilation results in a so-called "transposition," the resultant combination having a valid 3:4 ratio, but not being the combination that was transmitted. Fortunately, the probability of occurrence of such transpositions is small. On accuracy of transmission, see Chap. 27.

8. Error-correcting Codes.[7,8] Usually these are two-condition codes in which each combination is so constructed that the occurrence of a specified type of single or multiple mutilation—one or more unit elements changed—will not only be detected but can be interpreted by the receiving decoder or converter in such a manner that there is a high probability that the signal mutilation will not result in an error in the recorded information. This error-correcting feature is obtained by adding, to some or all of the basic code combinations, one or more so-called "check digits" or unit elements as required (see Chap. 27).

This type of code finds application in signaling or data-handling systems where its use may be preferable to manual or automatic request for a repetition of the mutilated characters. It is not used in commercial RT services, where the constant-ratio type of protected code is finding increasing application.

9. Code Conversion.[3,9,10] When it is necessary to transfer message traffic or other information from a system employing one code to a system employing a different code or type of code, the transfer may be effected either by manual transcription or

by automatic code conversion. The trend is to the use of automatic converters employing mechanical selection, electromechanical relays, electronic devices and circuits, or matrixes of various types. A few typical cases, of commercial importance, are mentioned below.

10. Morse and Five-unit.[9] This is a particularly difficult type of conversion because, as will be seen from the code charts of Figs. 1 and 2, the five-unit teleprinter code makes use of letters (lower case or shift) and figures (upper case or shift) assignments, whereas the Morse code provides only one assignment for each code combination.

11. Five-unit Variants. As shown in Fig. 2, assignments to letters and to machine functions are well standardized but the figures assignments vary considerably among keyboards used in various services. An outstanding case of considerable commercial importance is that of the International assignments employed in the European Telex service and overseas TEX (RCA) service vs. the assignments employed by the TWX service in the United States. Since a number of the figures appearing in one do not appear at all in the other, it is impossible to provide a complete character-for-character conversion. Such a case requires, in addition to direct conversions, mutual agreement on a number of suitable equivalences and arbitrary operating procedures whereby the transmitted intelligence can be correctly conveyed in the received copy.

12. Five-unit and Seven-unit.[3] This is a commercially important example of conversion between a protected and a nonprotected type of teleprinter code, the seven-unit protected code being used over many international radio circuits, and the five-unit nonprotected code in commercially available teleprinter equipment and over wire-line or other forwarding circuits. As will be seen from Fig. 2, conversion between the two codes requires merely a conversion between five-unit and seven-unit code combinations assigned to the same letter or function. The presently used assignment of seven-unit combinations was arranged specifically to facilitate conversion between these seven- and five-unit codes.

13. Business Codes. Business concerns that have a large volume of telegraphic communication commonly use standard "commercial codes" consisting of groups of letters arranged alphabetically, each group standing for a word, phrase, sentence, or other item of information. Typical examples are the ABC Code (6th edition), Bentley's, and Peterson International Code. There also are more specialized codes for certain industries or branches of commerce; and some concerns employ private codes to provide secrecy in addition to abbreviation. Morse press-wire operators used a standard list, known as the Phillips code, of extreme abbreviations of common English words.

KEYBOARDS

From Figs. 1 and 2, it will be apparent that keyboards of Morse-code perforators, and of teleprinters used in various services, must differ appreciably from one another and from the keyboard of a standard office typewriter. Keyboards for the international Morse code and for international teleprinter services are shown in Fig. 3. While the basic arrangement of the letter keys follows that of a standard office typewriter, the key assignments for numerals and other figures vary widely. This applies not only within the United States but also to machines used in a number of other countries.

Machines employing the six-unit Baudot code instead of the more usual five-unit have enlarged keyboards to accommodate the greater number of characters made possible by the available 64 code combinations. An example is Teletypesetter equipment. This keyboard is shown in Fig. 3 with a number of special characters and functions deleted to facilitate comparison with the other keyboards. The lower-case or unshift position of letter keys provides small letters, and the upper-case or shift position provides capital letters since, unlike telegraph practice, both are required in typesetting.

MODES OF OPERATION[11,13]

14. Morse. In RT services of the world, earlier art dictated the use of manual Morse operation in which the transmitting operator sends with a hand key and the

MORSE PERFORATOR
Creed Type 9W

5-UNIT TELEPRINTER
International No. 2

6-UNIT TELETYPESETTER
FIG. 3. Perforator and teleprinter keyboards. The six-unit Teletypesetter keyboard has 60 keys plus space bar. Assignments over numerals differ depending on service. Keys not marked provide special typesetting functions.

receiving operator copies by ear. This mode of operation still is used where necessitated by considerations of signal-to-noise ratio, practical operations, and economics. Point-to-point overseas commercial services, however, use mechanized Morse operation in which transmission is from perforated tape prepared by the transmitting operator, and reception is by reading and transcription from an up-and-down dot-dash ink record on a moving paper tape from a so-called ink recorder or undulator. Operating speeds may run as high as 300 or more words per minute (wpm).

15. Morse Direct Printer. To eliminate the necessity for manual transcription by a receiving operator, use has been made of a printing telegraph machine that operates directly from Morse code signals. A notable example is the Higgitt DCCC (double-current or two-condition cable code) system, still used by the British on their overseas RT network.

16. Teleprinter.[12] The use of teleprinter equipment employing equal-length codes of the Baudot and the constant-ratio types for commercial RT services has developed rapidly since about 1932. Among the reasons for this world-wide trend are availability of equipment, the need for mechanized operation and tape relay,[12] the difficulty of training Morse operators, protection afforded by the constant-ratio type of code,[6] and compatibility of structure of the nonprotected and protected codes.

17. Synchronous Operation. This does not require the addition of start and stop intervals preceding and following each combination of the basic codes shown in Fig. 2, but it does require relatively complex and expensive equipment at the terminal offices, and therefore is utilized chiefly on those overseas services on which the volume of traffic warrants the cost of the necessary equipment or where the particular service requires the use of protected-code operation such as the Automatic-RQ method discussed in Sec. 21. Synchronous terminal equipment generally is designed to provide two-channel or four-channel time-division multiplex (TDM) operation at approximately 60 wpm per channel. While special types of receiving printers have been used in such synchronous operations, present practice is to terminate each channel in standard start/stop terminal equipment, such as receiving printers or reperforators, or to extend one or more channels over wire-line or other start/stop circuits.

18. Start/Stop Operation (see Chap. 27). Where traffic volume or other service requirements neither dictate nor warrant the use of synchronous equipment, it is customary to employ the standard start/stop teleprinter machines and facilities widely used on wire-line services. This provides a single channel, at nominal speeds ranging from 60 to 100 wpm.

19. Nonprotected Operation. Standard types of five- and six-unit start/stop teleprinter equipment may be used on a single-channel basis over most radio facilities or may be used directly on the individual channels of time-division or frequency-division multiplex systems over important radio circuits. In either case, signal mutilations will cause errors in the received copy because of the nonprotected structure of the Baudot five- and six-unit codes.

20. Protected Operation. Commercial telegraph and other services often are called upon to provide a maximum of protection against errors due to signal mutilations. This is of particular importance over short-wave circuits, where signal-to-noise ratio and fading conditions vary greatly, and in any type of direct customer-to-customer service such as Overseas Teleprinter Exchange Service (TEX), leased channels, etc. Such protection appears to be provided most satisfactorily by the use of a constant-ratio type of protected code such as the 3 M–4 S form of seven-unit code described before. Such channels now are operated in so-called *diplex* pairs, on a two-channel synchronous basis, as required by the usual designs of Automatic-RQ (ARQ) equipment.[10]

21. Automatic-RQ.[10] This is a form of teleprinter operation employing a constant-ratio code in which detection of a mutilated character automatically prevents the receiving printer from functioning, initiates a request for repetition (RQ), stops transmission of traffic until the repetition is automatically provided from storage at the transmitting office and is correctly received, and then resumes normal transmission and reception. Its use requires that the two-way radio circuit be operable and functioning in both directions. Present-day designs of ARQ equipment operate such protected channels, in diplex pairs, over a two-channel or four-channel TDM system.

22. Multiplex. Whereas mechanized Morse operation made it possible to operate a good radio channel at speeds of 300 or more wpm, the use of teleprinter equipment limits each such channel to a speed of some 60 to 100 wpm. Efficient utilization of available frequency assignments and of radio transmitters, etc., makes it desirable and often necessary to employ so-called multiplex methods that permit the simultaneous operation of two or more teleprinter channels over one transmitter and frequency assignment. The two basic methods are time division and frequency division, combinations of the two systems sometimes being employed.

23. Time-division Multiplex[14,15,16] (see Chap. 27). Simultaneous transmission of two or more channels (messages) over a single carrier is effected by dividing the time duration of each single-channel unit interval into generally two, three, or four equal parts—for two-, three-, or four-channel operation—and utilizing these half- or third- or quarter-length intervals as unit elements of the multichannel, or so-called multiplex, aggregate signal (for details regarding modes of channeling, see Sec. 70). Each such aggregate-signal unit element carries the mark or the space intelligence of a full single-channel unit element of one of the individual channel signals. The multichannel aggregate keying is applied to a tone-frequency carrier, or to an RT transmitter, suitable for such high-speed keying as 120 or 240 wpm. At the distant receiving office, synchronous equipment breaks down the aggregate keying and delivers regenerated, single-channel signals to the separate receiving teleprinters for the individual channels. The number of channels is limited, in practice, by the maximum keying speed that can be handled satisfactorily over the facilities and circuits involved; multipath propagation on long-distance short-wave circuits generally sets a practical upper limit of four such TDM channels of nominally 60 wpm each.

24. Frequency-division Multiplex. The best-known form of FDM is the multitone voice-frequency carrier telegraph system employed over wire-line telephone networks and single-side-band (SSB) radio-telephone circuits, channel mid-band frequencies being spaced 120, 150, or 170 cps in different commercial systems. Each discrete tone carries the keying of a separate, start/stop teleprinter, all channels operate simultaneously and are separated at the terminal offices by electrical filters. Such a system provides flexibility and simplicity of direct interconnection between wire-line and radio services that employ start/stop teleprinter equipment of compatible design. Since the system does not involve time division, the maximum keying speed that must be handled over the radio circuit is that of any one tone channel. Where protected teleprinter operation is desired, the time-division diplex aggregate keying of a pair of ARQ channels may be applied to any tone of an FDM system, assuming there is adequate channel band width. In practice, the number of tone channels is limited by the reduction in received signal-to-noise ratio resulting from the necessity of reducing the power per channel on any given radio transmitter of fixed peak power rating as the number of channels is increased.

25. Twinplex.[17,18] This is a special form of two-channel multiplex in which channel distinction is achieved not by time division but by frequency separation in a special application of frequency-shift keying (FSK); four discrete frequencies are used to represent the four possible combinations of simultaneous M and S on the two channels. Keying of the two channels need not be, but preferably is, synchronized. More than two channels may be provided over one radio transmitter by extension of the basic method or by combining it with others.

KEYING SPEEDS

26. Definitions

Dot. The shortest (mark) element in codes such as the Morse code; the unit element in terms of which the length or time duration of dots, dashes, and spaces is measured.

Dot-cycle. A mark unit interval followed by a space unit interval, a dot-cycle per second being the unit in which keying frequency is expressed.

Unit Element or Unit Interval. In codes such as the Morse telegraph and the Baudot teleprinter code, the shortest or unit element or time interval used in forming code characters, each code character of the basic Baudot code consisting of five such unit elements or unit intervals.

Baudel. A term proposed, though not yet internationally accepted, to designate one unit element or unit interval in a telegraph or teleprinter code.

Baud. A unit of telegraphic signaling speed. The speed in Bauds is the number of unit elements, or unit intervals, per second, being numerically equal to twice the fundamental keying frequency expressed in dot-cycles per second. (A speed of 50 Bauds is equivalent to 25 dot-cycles per second.)

FIG. 4. Teleprinter speeds and timing.

Operations per Minute (Opm). In teleprinter operation, the number of letters, characters, or machine operations per minute. This is the number of teleprinter code combinations transmitted per minute.

Words per Minute (Wpm). In computing telegraph transmission speeds, a "word" is considered as consisting of five letters and one space, or a total of six code characters.

27. Relative Speeds.[2,3] The relationship between Baud and dot-cycle per second keying speeds, and wpm traffic speeds for various codes, may be tabulated as follows:

For 100 Baud Speed or 50 Dot-cycles/Sec

Code	Wpm
5-unit synchronous	200
2-condition cable code	143
7-unit synchronous	143
5-unit (7.5) start/stop	133
Morse	111*

* The value for Morse operation is empirical because of the differing lengths of Morse code characters. It is based on the average context of commercial telegrams. Another conversion factor often used is that 40 dot-cycles per sec is equivalent to 100 wpm Morse.

28. Speeds Attainable. These are determined by the mode of operation, signal-to-noise ratio, fidelity of M/S ratio, and traffic requirements.

Morse. Manual operation ranges roughly from 15 to 35 wpm, depending on signal conditions and on operator proficiency. In mechanized operation speeds normally range from 30 up to 300 wpm depending on signal conditions, equipment capabilities, and traffic requirements.

Morse Direct Printer. In the British Higgitt system, the operating speed of the synchronous equipment normally is fixed at 125 wpm total for the two channels (see Fig. 4, last line).

Teleprinter and Multiplex. The tabulation of Fig. 4 gives, for various types of teleprinter equipment and services, common operating speeds expressed in Bauds, dot-cycles per second equivalent keying frequency (cps), operations per minute (opm), and words per minute (wpm).

KEYING ANALYSIS AND BAND WIDTHS

29. On-Off Keying.[19,20,21,26] All telegraph keying basically is on-off. In most, if not all, systems the channel keying originates as two-condition on-off keying and although it may undergo transformations it must end up as a reasonably accurate reproduction of the original keying in the two-condition mode. Therefore the two-condition rectangular wave form of voltage or current is the basis for analyses of keying side bands, occupied and required band widths, etc. (Special cases, such as the "shaped" keying of on-off radio transmitters with class C power amplifiers, require analysis of trapezoidal or similar keying wave shapes.[20]) Rigorous mathematical treatment would require a transient analysis of individual unit elements or of longer intervals. For practical purposes, however, it is satisfactory to consider that a continuous and unbroken succession or "train" of rectangular dot-cycles represents the maximum keying-frequency components and band-width requirements.

30. Fourier Analysis. In a dot-cycle, the value of the current or voltage rises instantly to a steady on or M value, at which it remains for one half cycle, and then instantly drops to a steady off or S value and remains there for the following half cycle. A wave train of such rectangular dot-cycles may be analyzed as consisting of the fundamental keying (dot-cycle) frequency plus all odd harmonics thereof. The equation of the voltage wave is

$$e = \frac{4E}{\pi}\left(\sin x + \frac{1}{3}\sin 3x + \frac{1}{5}\sin 5x + \cdots\right)$$

which holds for values of x between $-\pi$ and $+\pi$. The first term, $\sin x$, represents the fundamental keying or dot-cycle frequency and, alone, provides merely a sinusoidal wave shape. The third, fifth, and succeeding terms, or harmonics of the

fundamental keying frequency, progressively steepen the rise and fall of the wave shape and flatten its top; the contribution of these terms becomes successively less significant as the order of the term increases. In practice, the fifth harmonic generally is the highest that is justified and that need be retained for a satisfactorily close approximation to the rectangular wave shape.

NOTE: Actual telegraphic keying contains M and S intervals ranging randomly from one to seven unit elements in length. The distribution of energy over the frequency spectrum therefore is not confined to the discrete odd-harmonic frequencies of a dot-cycle train but is more random within approximately the same frequency limits.

31. Band Width Occupied. Application of such a dot-cycle train of keying to a voice-frequency (v-f) tone carrier or to an r-f carrier produces the usual double-side-band signal of conventional amplitude modulation, the side bands extending out on each side of the carrier to a distance or frequency separation determined by the fundamental keying frequency and the number of its harmonics present in the keying wave shape or r-f envelope. Passage of the third harmonic, for example, results in an occupied band width of six times the fundamental (dot-cycle) keying frequency. The economics of wire-line operation, the growing congestion and demand for channels in the radio spectrum, and the necessity for reduction of interference and cross talk all dictate that the occupied band width be held to a minimum for the particular service. This requires that the rise and fall of the M-S and S-M transitions be made less abrupt and less steep or, viewed differently, that the higher-order harmonics of the keying frequency be suppressed. This is accomplished by the use of suitable low-pass filters or band-pass filters or of simpler *smoothing circuits*. In the case of most transmitters, for on-off keying, the practical limit of such reduction is a compromise between what is technically desirable and what is economically feasible.[21,26]

32. Signal Shaping. Shaping of the transmitted radio signal, as recommended by the CCIR (Geneva, 1951),[21] is specified as follows:

For single channel, a-m, c-w telegraphy (class A1) using Morse code, when large fluctuations of the field strength are present:

2.1.1 *Band width necessarily occupied.* The band width necessarily occupied is equal to five times the keying speed in Bauds (later referred to as B) with an attenuation of the components at the edges of the band equal to at least 3 db, in comparison with the level of the same components of the spectrum representing a series of equal rectangular dots and spaces at the same keying speed. This relative level of −3 db corresponds to an absolute level of 27 db below the level of a continuous mark.

2.1.2 *Spectrum of the out-of-band radiation.* Outside the band width defined above, the envelope of the spectrum should lie below a curve starting at the points (±5B/2, −27 db) defined above, and presenting a slope of 30 db per octave and extending over at least one octave, that is, out to the points (±5B, −57 db). From these points onward, the level of all components emitted should be below −57 db.

2.1.3 *Build-up time of the signal.* The spectrum limited precisely as described above corresponds to a build-up time of the signal equal to about 15 per cent of the initial duration of the telegraph dot. This build-up time is likely to vary slightly around that figure, depending upon the exact nature of the filters employed for the shaping of the signals.

33. Band Width Required. This is determined by the fundamental keying frequency—in dot-cycles per second—and the steepness of M-S and S-M transition required by the equipment or service in question.

Where the amplitude of the received signal is stable, the transition response of the receiving equipment can be maintained at the halfway points on the rise and fall of the voltage waves. The latter then need not be steep, a sine wave or something slightly better being satisfactory for reproduction of the required 50:50 ratio of M/S. For a dot-cycle train, this requires only the fundamental keying frequency. For somewhat more tolerance and better performance on random telegraph keying, practical design often allows for passage of the equivalent of the second harmonic of the fundamental dot-cycle frequency.

Where signal amplitudes vary widely and rapidly, as is common in the case of short-wave signals, the transition response of the receiving equipment effectively slides up and down on the slope of the M-S and S-M transitions in the signal. The M/S ratio then can be held constant at the desired 50:50 value only by provision of a rectangular keying wave shape. This would contain numerous high-order harmonics that would occupy a very wide band and cause interference. A compromise therefore is necessary. Generally speaking, it is satisfactory to hold the M/S ratio within the limits 40:60 to 60:40 at the output of the radio receiver and associated electric circuits, amplifiers, rectifiers, etc. Because of the difficulty of specifying exact wave shapes required in all cases, the Radio Regulations (Atlantic City, 1947) merely stated that for nonfading circuits the third harmonic should be passed, and for fading circuits the fifth. This would require total band widths of, respectively, six and ten times the fundamental keying frequency. Those values today are considered highly conservative and somewhat excessive for commercial operations; the tendency now is to use all possible means for minimizing variations in signal amplitude and to compromise on the third harmonic as the desirable upper limit.

The M/S ratio of the signal, as transmitted or as it arrives at the distant end of a short-wave circuit subject to multipath propagation, may differ appreciably from the ideal 50:50 value. In such cases, either the M or the S intervals in the signal will be elongated and the others shortened. To handle these shortened elements satisfactorily requires a somewhat greater band width in the receiving equipment and associated system. A commonly used approximation has been to calculate an equivalent dot-cycle keying frequency from the length, in milliseconds, of the shortest M or S elements of the incoming signal. This then is used in the usual Fourier analysis.

A more generalized approach to the problem of determining the electrical band width required is based on the permissible slope of the M-S and S-M transitions of the keying wave shape. The method is particularly applicable in cases of mechanized operation, such as teleprinter radio services, where the mechanism of the final utilization device—such as a receiving printer or reperforator—will tolerate no more than a specified maximum of signal elongation or shortening. From this maximum or total there is deducted the value measured or observed on the actual incoming signal. The remainder is the amount of elongation which may be permitted because of the limited band width of the receiving system. By assigning this value to an arbitrarily chosen portion of the transition slope—say from the 10 to the 90 per cent amplitude points on the slope—it is possible to calculate the band width required in i-f filters, etc. The required total (double-side-band) band width, in cps, is approximately equal to 1,000 divided by the number of milliseconds elongation which may be tolerated in the electrical filters, etc., of the receiving equipment and system. For example, if the total permissible elongation is 7.5 millisec, and transmitter maladjustment or multipath propagation introduces 5-millisec elongation, the remaining permissible 2.5 millisec requires a receiver band width of approximately 400 cps. This type of calculation may also be applied to the over-all system comprising transmitter and receiver.

It should be pointed out that any such calculations of required band width, for typical short-wave RT signals, usually involve so many assumptions and approximations that, to the practical man, they must be considered as guides rather than as scientifically exact values. The safe procedure, therefore, is to conduct an experimental check under actual operating conditions.

34. Two-frequency Keying. This method, which sometimes is loosely though erroneously referred to as a form of FSK, is essentially a form of on-off keying in which the mark frequency source is keyed on and the space frequency source simultaneously is keyed off, or vice versa. Side-band and energy distribution, therefore, is that of two carriers being keyed on-off at the speed in use. Since the phase relationship between the two sources generally is uncontrolled, and therefore random, there is a phase discontinuity at transition. This is a possible source of out-of-band

spurious radiation that can cause interference. Furthermore, it is necessary to shape the keying envelope of each M and S suitably to suppress high-order harmonics of the keying frequency that otherwise would cause interference. During the transition interval between such shaped envelopes, the random phase relationship causes either addition or cancellation. This results in a variation in the exact timing of the effective transition. In some cases, at high keying speeds, this may be objectionable.

35. Frequency-shift Keying (FSK).[22–29] This is a form of true f.m., in which the frequency of a single source—an oscillator—is shifted from one frequency to another. For two-condition code this shifting may be from S to M to S or it may be both up and down from a neutral "carrier" frequency midway between the steady M and S frequencies. Since the method is a true f.m., abruptness or smoothness of transition from one frequency to another may be controlled by suitably shaping the wave form of the keying voltage applied to the FSK modulation stage. The resultant FSK signal, being of variable frequency but constant amplitude, then may be passed through class C power amplifiers without affecting the keying envelope shape. Side-band energy distribution thus is determined and controlled by the wave shape of the applied keying and the inherent characteristics of the linear frequency-modulator stage.

36. Bessel-function Analysis. The usual analysis of f.m. is based on the concept of an unmodulated "carrier" midway between the upper and lower shift limits (M and S) of the FSK signal. This unmodulated carrier may be either real or fictitious. In either case, the analysis is the same. Frequency deviation ΔF is reckoned plus and minus from the carrier frequency. The deviation therefore is equal to one-half the value of total frequency shift between M and S, a total shift of 400 cps being a deviation (plus and minus) of 200 cps. Designating the carrier frequency as F, the deviation as ΔF, and the modulating frequency as f, the ratio $\Delta F/f$ is known as the *deviation ratio* or *modulation index*. Side-band distribution is a function of this deviation ratio, the complete theory being given in standard texts on the subject.[27] Data for some typical cases are given in the tabulation below, which is for single-frequency sine-wave modulation.

Deviation ratio $\Delta F/f$	% of unmodulated carrier voltage							
	Carrier	$F \pm f$	$F \pm 2f$	$F \pm 3f$	$F \pm 4f$	$F \pm 5f$	$F \pm 6f$	$F \pm 7f$
0.5	94	24	3.1					
1.0	77	44	11.5	1.96				
2.0	22	58	35	12.9	3.4			
3.0	26	34	49	31	13.2	4.3	1.14	
4.0	40	6.6	36	43	28	13.2	4.9	1.52

More extensive tables of these Bessel functions are available in the literature,[20,27] the usual mathematical terminology for any one coefficient being in the form $J_n(m)$, which designates the Bessel function, of the first kind, of argument m and order n. The argument m is taken as the deviation ratio $\Delta F/f$. The order n, which is the order of the term or side band, is zero for the carrier, 1 for the first pair of side bands at $F \pm f$, 2 for the second pair at $F \pm 2f$, etc.

37. Band Width Occupied for FSK. The above tabulation of FSK side-band amplitudes shows the total band width occupied when an FSK signal is produced by a theoretically perfect f-m modulator, supplied with sine-wave keying at a fundamental keying or dot-cycle frequency f, for various values of frequency deviation ΔF. The full significance can best be brought out by an example. Assume a fundamental keying frequency f of 100 dot-cycles per sec and a total frequency shift, from M to S, of 400 cps. The deviation ΔF then is 200 cps and the deviation ratio is 200:100 or 2.0. The M and S frequencies are at $F \pm 2f$, respectively, and keying side bands of

appreciable amplitude extend to $F \pm 4f$, which is $2f$ beyond the steady M and S frequencies. This is fairly typical of certain present-day commercial operations. At very low values of deviation ratio, below 0.5, the total occupied band width is twice the applied sine-wave keying frequency. At high values of deviation ratio, above 4, side bands of appreciable amplitude extend to values of from $3f$ up to $5f$ outside the steady M and S frequencies.

In RT practice, the wave form of the keying voltage applied to the FS modulator is not sinusoidal but contains harmonics (see Secs. 39 and 40 of Chap. 1) necessary to provide a dot shape that tends more toward the rectangular. Rigorous mathematical analysis of such cases is quite involved and indicates not only resultant components corresponding to the terms of the Fourier expression for the keying wave shape but also components having sum and difference frequencies. The total occupied band width can be approximately determined by considering the value of $\Delta F/f$ not only for the fundamental dot-cycle keying frequency but also, individually, for each of the keying-frequency harmonics in the wave shape of the applied keying voltage. For actual telegraphic keying, where the lengths of M and S intervals range randomly from one to seven unit elements, the energy will not be concentrated on discrete side-band frequencies but will be spread out more at random over the approximate maximum band width indicated by the foregoing analysis for the case of a dot-cycle train.

Side bands extending by undesired amounts beyond the steady M and S frequencies may be suppressed, or reduced, by two general methods. One is to shape the applied d-c keying wave form suitably at the input to the FSK modulator by the use of a low-pass filter. It should be noted, however, that this will have no effect on the production of FSK side bands inherent in f.m. as tabulated in a foregoing paragraph. Such side bands, produced in the FSK modulator or keying stage, can be suppressed or reduced only by the use of a band-pass filter following the modulator stage. This is feasible where the frequency shifting is accomplished at relatively low frequencies, say in the i-f or the v-f range.

38. Band Width Required for FSK. While wire-line practice has arrived at definite answers to the question of band width required for a specified speed of FS keying and type of service,[29] the situation in the short-wave field is not so stabilized. Attempts to obtain international agreement on values of frequency shift, through the International Radio Consultative Committee (Geneva, 1951), resulted in recommendations that necessarily took into account not only technical facts but also operating systems and practices current, at that time, throughout the world. Refinement and simplification of those original recommendations is an evolutionary process that may require some years. Meanwhile, simplified analyses, approximations, and experimental or operating results must serve as a guide to the designer and the practical man.

A total frequency shift of 850 cps was in general use during and following the Second World War when FSK came into widespread use over short-wave circuits. This was used for all keying speeds ranging from slow-speed hand keying to some 85 cps for four-channel TDM. For the latter, this meant an occupied band width of some 1,360 cps. Even a single-channel printer signal, keying at approximately 22 cps, occupied a 1,070-cps band width. Today, with the growing congestion of channels and demand for allocations, these band-width requirements are considered excessive.

Recommended values of total shift (CCIR Geneva, 1951) constitute two series of numbers, *viz.*, 70, 140, 280, 560, 840 cps and 100, 200, 400 cps. Other existing systems employ other values. One such series is 85, 170, 340 cps.

NOTE: CCIR Warsaw, 1956, Recommendation No. 150 specifies preferred values of total shift as 200, 400, and 500 cps; and that values of 140, 280, and 560 may be used provisionally, but that 560 cps should not be adopted for new systems, no mention being made of the 840-cps value.

Maximum utilization of available spectrum space and of channel allocations and the necessity of reducing interference to a minimum indicate the use of the smallest

practicable value of frequency shift for any given service. This might be a deviation ratio of 1.0 or even less. Such small values of total frequency shift, however, run into practical difficulties in the design of transmitters and receivers. Sinusoidal keying also would seem desirable but, particularly at the higher keying speeds such as four-channel TDM, results are more adversely affected by multipath propagation than when the keying wave shape is more nearly rectangular.

While long-term efforts are directed toward the use of minimum values of shift, present practice and trends in commercial application are somewhat more conservative; a reasonable compromise appears to be the use of a deviation ratio of 2.0 at the highest keying speed to be handled by a given radio transmitter or over any one channel thereon. This might, for example, be a total shift of 400 cps for a keying speed of 200 Bauds or 100 dot-cycles per sec. The wave shape of the keying voltage supplied to the FS modulator or keying stage preferably should be shaped by a low-pass filter that will pass no more than the third harmonic of the fundamental keying frequency ($3 \times 100 = 300$ cps).

Twinplex Channeling

Channel A	Channel B	Frequency deviation, cps
Mark	Mark	+600
Mark	Space	+200
Space	Mark	−200
Space	Space	−600

39. Twinplex.[17,18] This is a four-condition mode of FSK (see Sec. 25). The four discrete frequencies, representing the four possible combinations of simultaneous M and S on the two channels, are spaced 400 cps apart, total shift between the highest and lowest thus being 1,200 cps. In a typical application employing a standard 60-wpm teleprinter on each of the two channels, total band width occupied by the frequency shift plus the keying side bands is stated to be approximately 1,700 cps.

KEYING FIDELITY

40. Mark/Space Ratio. Correct and reliable interpretation of received signals, whether by ear or by transcription from an ink-recorder tape record or by machine, requires that the ideal M/S ratio of 50:50 for a dot-cycle be maintained as closely as is practicable. For Morse operations, a range of 60:40 (heavy) to 40:60 (light) is considered generally satisfactory. This is for the entire system and circuit, including all associated transmitting and receiving facilities and the radio path. To maintain this over-all fidelity, it is essential that each link and piece of equipment be appreciably better than the required over-all fidelity, the degree being dependent on the number of contributing elements that make up the whole. While, sometimes, it is possible to correct for heavy or light keying, by compensating adjustments of relays or keying devices in other portions of the over-all circuit, this practice is not recommended because it introduces confusion and resultant delays when facilities must be switched or interchanged. At the slower keying speeds, up to 60 wpm or roughly 25 dot-cycles per sec, the use of electromechanical relays is fairly common and generally satisfactory. While such relays may be used at double that speed, or even higher, the increasing difficulty of maintaining critical adjustments makes such operation generally inadvisable. Present-day practice favors the use of electron-tube, or equivalent, types of keying circuits since these can be designed to provide any required degree of fidelity at even the highest keying speeds.

Checking of the M/S ratio requires suitable monitoring and measuring equipment. For the slower speeds, this may be an ink recorder. At the higher speeds, in particular, a cathode-ray oscilloscope should be used. This has the added advantage of clearly showing the exact wave shape of the keying and all details of minor distortions. The necessity for such a high-speed monitoring and measuring instrument will be understood when it is realized that the entire time duration of a dot, at speeds such as four-channel time-division multiplex keying, may amount to less than 6 millisec (see Fig. 4).

High vs. Very Low Frequencies. The v-l-f services had certain advantages: (1) freedom from interruption due to ionospheric disturbances; (2) 24-hr and year-round operation on a single frequency; and (3) steadiness of signal strengths. Disadvantages were: (1) high cost of transmitting equipment and antennas; (2) high power consumption; (3) relatively low keying speeds; and (4) slowing down or complete stoppage by high levels of atmospheric static, particularly where summer lightning storms were prevalent in the direction of reception. The h-f services also have certain disadvantages: (1) interruption of service by severe ionospheric disturbances, (2) fading, (3) multipath propagation, and (4) necessity for having several frequencies for each circuit to provide 24-hr service the year round and through the sunspot cycle. These disadvantages, however, are far outweighed by the advantages, which include: (1) comparatively low cost, particularly of transmitting equipment and antennas; (2) comparatively low power consumption; (3) high keying-speed capabilities; (4) practicability of highly directive antennas for transmission and for reception; and (5) flexibility of operations.

High Frequency. The outstanding feature of radio propagation in the h-f range, from nominally 3,000 to 30,000 kc, is the relatively low power required for communication over long distances. Typical transoceanic circuits, ranging from 2,000 to 10,000 miles in length, are operated with transmitters rated at from 1 to 50 kw output. Because of the extreme ranges of signal attenuation for such ionospheric or sky-wave propagation,[36] the primary requirement is a proper choice of frequency suitable for the particular circuit (path), time of day, season of the year, and portion of the sunspot cycle. Predicted frequency requirements, both long- and short-term, are issued regularly by government and commercial agencies. Highly directive transmitting antennas concentrate the radiated power in narrow beams, to provide maximum gain and thereby maximum signal strength at the distant receiving station. Receiving antennas preferably are of a directive type providing good signal pickup in the desired direction, and maximum protection against both interference and noise from directions other than the desired one. Diversity reception, preferably space diversity,[37,38] is employed to minimize the effects of short-period fading which normally may cover a 30-db range in amplitude. The use of FSK, instead of on-off keying, provides further improvement[25,39] variously estimated up to 11 db in terms of transmitter power for a given error count in the received signal. Lastly, the question of power rating of the radio transmitter must be decided from considerations of (1) minimum power required to provide the desired type and quality of service over the paths in question, (2) improvement in quality and hours of service obtainable by a given increase in power, and (3) what is economically justified. Required values of received signal strength depend somewhat on noise characteristics of the receiving site and range approximately from 0.1 μv per m for slow-speed aural reception to 5 μv per m for high-speed mechanized operation. Values normally obtained in practice range from effectively zero up to 100 μv per m or even 1,000 μv per m, depending on propagation conditions.

45. Medium-distance Point-to-point Services. In high northern latitudes, where h-f sky-wave propagation is frequently and severely disturbed by auroral phenomena, communication over distances of up to some 1,500 miles often is carried on by means of so-called "surface-wave" transmission at frequencies of approximately 100 to 150 kc. In less disturbed areas, where sky-wave propagation is more reliable, frequencies of from 1,000 to 3,000 kc are employed during the daytime and of from 3,000 to 8,000 kc at night.

46. Short-distance Point-to-point Services. In commercial RT services, the use of frequencies in the v-h-f, u-h-f, and s-h-f ranges is confined chiefly to the remote-control links between central office and the outlying h-f radio stations proper. To handle the required large number of individual telegraph channels over one such carrier, it is necessary to employ some form either of frequency division, such as voice-frequency carrier telegraph techniques, or of pulse-modulation multiplexing.[40] Highly directive antennas, employed for transmission and reception, provide excellent

signal-to-noise ratios for very small amounts of power. Sometimes it is necessary, however, to employ two vertically spaced receiving antennas for space-diversity reception to provide protection against deep fades. At the frequencies generally employed, propagation is essentially line-of-sight and therefore requires the use of repeater stations, ordinarily spaced some 20 to 50 miles apart, the distance being dependent on antenna heights and on the intervening terrain or other obstacles.

Other examples of such line-of-sight operation in the u-h-f and higher-frequency ranges for telegraphic and teleprinter services include radio-relay systems to replace wire-line facilities over heavily loaded trunk routes of domestic telegraph systems[40] and teleprinter communication channels over radio-relay facilities associated with oil pipeline and similar operations in open country or undeveloped areas and over rugged terrain.

47. Mobile Services. Of the three classifications of mobile services, aeronautical, land, and maritime, the oldest and major user of RT communications is the maritime. Commercial services to and between ships employ manual operation except on the largest ships and at major coastal stations where mechanized Morse or printer operation may be available when a large volume of traffic is to be handled and when radio conditions permit. Because of the large number of ships, the limited number of frequency assignments which must be shared, the intermittent nature of the service, and the need to be able to give emergency or distress calls priority, both transmission and reception are handled by, or are under the direct control of, one operator. At major coastal stations, the operator is located at the radio receiver but he remotely controls and keys the transmitters. To permit simultaneous transmission and reception without interference, the transmitters sometimes have been located as far as 50 miles from the main receiving station.

Frequencies generally utilized heretofore for short-distance working by the maritime services lie within the range 350 to 500 kc, the 500-kc frequency being internationally reserved for calling and for distress. A coastal station equipped with such transmitters rated at 5 kw, for example, has a normal daylight range of around 500 miles and a maximum nighttime range of several thousand miles under very favorable conditions on this frequency band. The ranges of shipboard transmitters are somewhat shorter unless working a shore station that is equipped with the best receivers and directional antennas. A frequency of around 150 kc formerly was used by the larger ships for communication over distances of from 1,500 to 3,000 miles under favorable propagation conditions. Present-day practice is to use frequencies in the h-f range (see International Table of Frequency Allocations, Atlantic City, 1947) for long-distance communication in the maritime services. This is because of the great distances that can be covered, with relatively low powered transmitters at these higher frequencies.

The aeronautical services normally employ radiotelegraph communication with airplanes on long overwater flights, teleprinter operation being used for point-to-point communication between fixed stations.

Land mobile service includes two main categories, namely, the Land Transportation Radio Services and the Public Safety Radio Services. These operate on assigned channels in the v-h-f and u-h-f bands and employ radiotelephony rather than radiotelegraphy.

48. Autoalarm.[41] This is an internationally established distress signal for use in the maritime services which is transmitted by hand or by an automatic keying device associated with a main or emergency shipboard transmitter, and which can be received and identified by an unattended autoalarm receiver (see Chap. 19) that will then cause an alarm to sound. The distress signal consists of a series of at least twelve 4-sec dashes separated by 1-sec spaces, transmitted as a tone-modulated c-w emission on 500 kc. American designs of such autoalarm receivers actuate the alarm upon receipt and identification of four such dashes.*

* For special "Alarm Signal for Use on the Maritime Radiotelephony Distress Frequency 2182 kc/s" refer to CCIR Recommendation No. 71, Geneva, 1951.

RADIO TRANSMITTING SYSTEMS

49. Classification. Historically, RT systems and equipment may be classified according to the methods employed to generate the r-f power. Spark transmitters, employing various types of fixed and rotary spark gaps, were once used for all classes of service. Arc transmitters later were employed for long- and medium-distance point-to-point operations and in the marine service. H-f alternators, such as the Alexanderson and the Goldschmidt, were used for v-l-f long-distance point-to-point services as on the international transoceanic circuits. Of these older methods, only the h-f alternator still is in use at a few locations; the others are now obsolete. Descriptions and technical details of such methods and equipment will be found in the older literature.

Tube transmitters, universally used today, may be classified roughly according to type of service (see preceding sections), power output, and method of modulation and of keying. An outline, convenient for the present purpose, is as follows:

- Type of service:
  - Long-distance point-to-point
    - V-l-f
    - H-f
  - Marine
    - Coastal
      - L-f
      - M-f
      - H-f
    - Shipboard
      - L-f
      - M-f
      - H-f
  - U-h-f and microwave relay
    - U-h-f
    - S-h-f
- Power:
  - High
  - Medium
  - Low
- Modulation:
  - Amplitude
    - On-off; class C amplifiers
    - Tone (SSB); linear amplifiers
    - Synthetic SSB
  - Frequency
    - FSK
    - Twinplex
  - Phase
  - Special combinations

50. Power vs. Type of Service. Nominal power-output ratings of radio transmitters, not including power gain of the antennas, may be stated approximately as follows:

Microwave relay	1–5 watts
U-h-f and v-h-f	5–50 watts
Marine:	
Shipboard	100 w–10 kw
Coastal	1–20 kw
Point-to-point:	
H-f	1–50 kw
V-l-f	100–1,000 kw

For the purposes of this chapter it is appropriate to treat radio transmitters from the viewpoint of basic methods. Following sections will therefore be devoted to the various basic methods of modulation and keying and their application to the peculiar requirements of telegraphic service.

51. Amplitude Modulation. *On-Off Keying.* Tube transmitters for this class of service are characterized by the use of nonlinear stages, buffers, frequency doublers and triplers, and class C power amplifiers, following the modulated or keyed low-power stage. Keying may be accomplished by use of an electromechanical relay or preferably, particularly at keying speeds much above 60 wpm or 25 dot-cycles per sec, by the use of a tube keyer. An example of the latter is shown, in circuit form, in Fig. 5. Rounding off square corners of the keying wave shape to reduce its harmonic content may be accomplished by a low-pass filter or an RC circuit ahead of the grid of the d-c keying tube or by use of similar smoothing in the plate supply to this tube. It must be pointed out, however, that the beneficial effects of such smoothing are largely if not completely lost as the r-f signal passes through the

following nonlinear stages that again "square up" the keying envelope of the r-f wave. Therefore, it is customary to place some smoothing or filtering in the d-c plate supply to the final class C power-amplifier stage (for keying analysis and CCIR recommendations, see Sec. 32). However, the inherent voltage regulation of power supplies for plate and bias d-c voltages must be good to prevent the undesired production of triangular or other unsymmetrically shaped keying envelopes of the final r-f output signal.

Fig. 5. On-off tube keyer for transmitter.

Tone SSB. The so-called single-side-band radio transmitter (SSB) is essentially a telephone-type transmitter in which amplitude modulation of the carrier is effected at a suitably low frequency—usually 100 kc or lower—at which it is practicable to filter off and reject one set of side bands and also to suppress the carrier. The resulting SSB signal then is stepped up in frequency by passage through additional modulator stages until the final output frequency is attained. These linear modulators operate at relatively low power levels and are followed by one or more linear amplifiers at the final output frequency. Power output is rated in terms of peak envelope power. This ordinarily is on the order of 2 kw or, with special power amplifiers, may be 20 kw or higher.

For telegraphic or teleprinter services, one voice band of nominally 3 kc is split up into a number of narrower channels by the use of standard v-f carrier-telegraph techniques and filters, the maximum number of such individual channels being determined by the useful band width required on each channel, by the mid-channel spacings, and by the extent to which it is considered permissible to sacrifice signal-to-noise ratio due to division of the total available power between the channels to be used. Practical calculation of this division of the peak envelope power to obtain the level permissible for the tone signal on each channel takes into consideration the small probability that modulation peaks on several or more channels may occur simultaneously. Therefore, it is often satisfactory to make this division not on a peak-voltage basis but rather on a peak-power basis, the peak envelope power being divided by the number of channels. The following tabulation gives both, the 3-, 6-, 9-db values being upper limits on a power-division basis, and the 6-, 12-, 18-db figures being the conservative lower limits on a voltage-division basis.

No. of Tone Telegraph Channels	Channel Level
1	0 db
2	−3 to −6 db
4	−6 to −12 db
8	−9 to −18 db

Keying of the carrier tone for any channel may, of course, be on-off or FSK.

Synthetic SSB.[42] This is a method for producing a high-power SSB signal from conventional designs of double-side-band telephone-type h-f transmitters employing class C r-f amplifiers and high-level amplitude modulation. A suitable adaptor unit, such as the Kahn,[42] generates a true SSB signal at low power level and then separates it into two components—an a-m component and a p-m component. The p-m component is substituted for the output of the conventional frequency source or drive and is amplified by the class C power stages of the transmitter. The a-m component is amplified through the normal voice-frequency amplifiers and high-level

amplitude modulator. With proper relative phasing and proportioning of the two components, the resultant output from the high-level modulator is an exact, but highly amplified, reproduction of the original SSB signal. The method is mentioned here because of its ready adaptability to conventional designs of h-f telegraph or telephone transmitters.

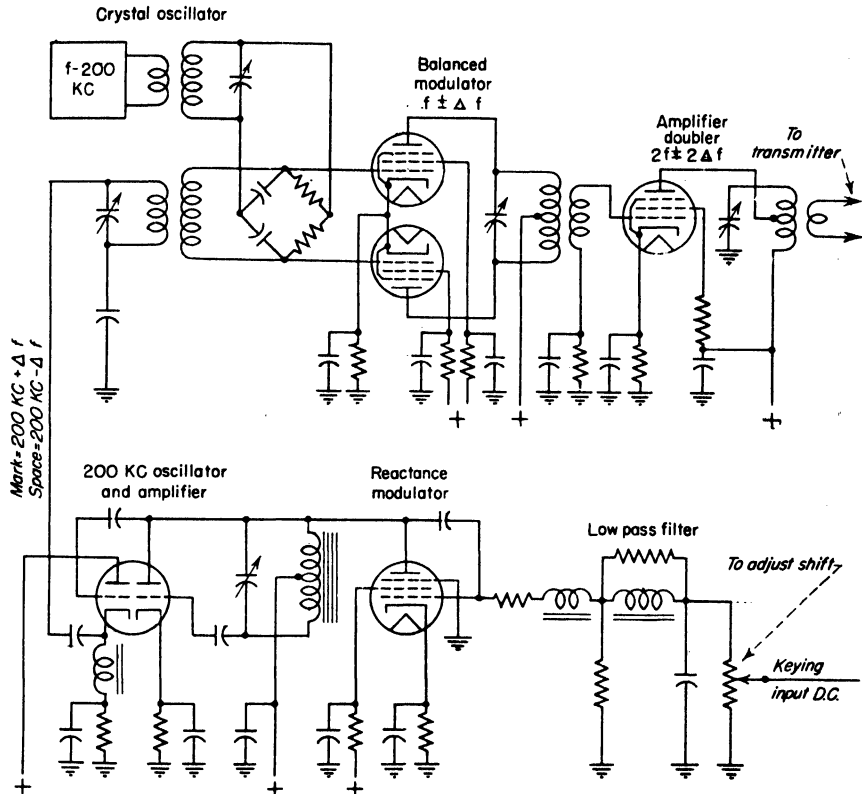
52. Frequency Modulation. Radio transmitters for FSK employ nonlinear class C r-f amplifiers but, unlike those for on-off keying, do not require good voltage regulation of the high-voltage d-c power supplies. This is because the amplitude of the r-f signal


FIG. 6. FSK exciter or drive unit.

is constant, only the frequency changing in accordance with the keying. A commonly used method of generating the desired FSK signal is to replace the conventional crystal-oscillator drive by an FSK exciter or drive unit. Such a unit is shown, schematically, in Fig. 6. The new crystal oscillator, in the FSK exciter, delivers energy at a frequency 200 kc lower than the required submultiple F/n (where n may be 2, 4, or 8, for example) of the final radio frequency. This then is combined, in a balanced modulator stage, with the $200 \pm \Delta F/n$ frequency from a reactance-tube-modulated 200-kc oscillator, the upper set of side bands $(F/n - 200) + (200 \pm \Delta F/n)$ or $F/n \pm \Delta F/n$ being selected and amplified. Frequency multiplication of n times in the multiplier stages of the radio transmitter proper then produces the desired final signal of frequency $F \pm \Delta F$, which is a central carrier frequency F and a total shift, between mark and space, of $2\,\Delta F$.*

* For a discussion of shift values recommended, and resulting band widths, refer to Sec. 38.

Twinplex.[17,18] This system, which is analyzed as regards keying characteristics and band-width requirements in Sec. 39, utilizes an h-f radio transmitter with associated FSK circuits capable of linear shift over a range of something greater than 1,200 cps. With this, there is required a Twinplex combiner which converts and combines the M-S keying of two individual Morse or teleprinter channels into a single four-condition or four-valued d-c signal to drive the linear FSK modulator or keyer stage. Combination is effected by connecting in series the d-c keyed outputs of channels A and B obtained from suitable tone-signal converters. By adjusting the space output of channel A to say 2 volts, and that of channel B to say 1 volt—the mark condition on each being zero volts output—the additive output of the combiner will be as tabulated below. The corresponding values of frequency deviation, in the final output signal, are given in the right-hand column.

Channel		Combined d-c volts	Frequency deviation, cps
A	B		
Mark	Mark	0	+600
Mark	Space	1	+200
Space	Mark	2	−200
Space	Space	3	−600

53. Phase Modulation. The use of approximately 1 radian of phase modulation of the r-f signal at a modulation rate of some 600 cps formerly was quite common on h-f transmitters for on-off keying. This produced a rather wide distribution of the emitted power over a frequency band roughly limited to the channel assignment, the purpose being to provide a form of frequency diversity which could be utilized to reduce the ill effects of fading. The method had value in those cases where reception necessarily was on a single receiver rather than on two or more employed in space diversity. It has been supplanted by modern FSK methods of operation.

Phase shift, instead of frequency shift, has been proposed as a method of transmitting telegraph or teleprinter code signals, the scheme being to shift the phase of a tone frequency, with respect to a fixed reference, by specific discrete amounts to provide one or more channels over a single carrier tone. This would correspond to single-channel and Twinplex modes, respectively, of FSK operation.

54. Special Combinations. Of the various possible combinations of FSK, a.m., on-off keying, and f.m., the best known and most widely used probably is that in which FSK is employed on each of the two or more tones that amplitude-modulate a conventional SSB telephone transmitter.

A less widely used combination is that of the *Twinmode*[17,18] system in which a single r-f carrier is frequency-shifted by one Twinplex (two-channel) keying aggregate and simultaneously is amplitude-modulated by a tone that itself is frequency-shifted by another Twinplex keying aggregate, the particular combination providing four Morse or teleprinter channels over the one r-f carrier.

RADIO RECEIVING SYSTEMS

55. General Characteristics. The broad subject of receiving systems, and radio receiving equipment, is dealt with comprehensively in Chap. 19. The present treatment, therefore, is restricted to those features which are peculiar to, or are of particular importance in, the reception of Morse and teleprinter code signals.

V-l-f reception, at frequencies below 30 kc, is characterized by the use of receivers that will provide the selectivity necessary to separate signals successfully on the 200-cps separation commonly assigned. As a result, permissible keying speeds are relatively low, a practical top figure for this channel spacing being approximately 75 wpm Morse. Another limitation on operating speeds and on the use of teleprinters is the severity of static during the season of the year when lightning storms are prevalent. In the fixed point-to-point v-l-f services, it has been customary to use directive receiving antennas such as the Beverage wave antenna,[43] loops, etc.

The maritime services employ RT receivers which operate in the v-l-f, l-f, and m-f

ranges, covering from 15 to 650 kc. These may be of autodyne or of heterodyne types, designed for convenient tuning and adjustment by the receiving operator, and of emergency and autoalarm types for use on the 500-kc distress frequency. Selectivity may be fixed or adjustable to suit the particular type of service or to provide maximum discrimination against interference.

H-f receivers, to cover the range of 2 or 3 Mc to nominally 30 Mc, vary greatly in details of design to suit the particular service and type of installation. These range from the relatively simple and small receivers of conventional design, suitable for shipboard installations, to the more elaborate types of highly specialized design required by the fixed, point-to-point services. The latter include many features that involve basic design considerations peculiar to the reception of code signals. They will be treated in some detail.

56. H-f Point-to-point Reception. Mechanized operation, particularly five-unit start/stop teleprinter, requires that the receiving system and equipment be designed to have the maximum accuracy and reliability. Since this applies to each unit element (Baudel) in every code combination transmitted, the required accuracy or fidelity of reproduction is, in certain respects, greater than for voice communication. Errors resulting from signal mutilations, due to causes such as noise or fading, should be held to no more than one per thousand words, or 1 in 6,000 characters, for commercially acceptable teleprinter service (see Chap. 27). This requires that not only the average but also the instantaneous signal-to-noise ratio be maintained above the workable minimum, and that the receiving equipment be designed to function and respond properly regardless of wide variations in either average or instantaneous signal level. Directive antennas, employed to minimize interference and noise, may be of such types as the vertical curtain with reflector, the so-called "fishbone" or wave antenna, and the rhombic (see Chap. 20). The receiving station, with its antennas, should be located outside any city and at a distance from radio transmitting stations, high-voltage power lines, and main highways. This is to ensure that local interference and man-made "noise" will be at a minimum.

57. Diversity Reception.[37,38] Instantaneous values of signal strength may normally be expected to vary over a 30-db range in amplitude, such short-period variations or fading having time durations on the order of seconds or fractions of a second—from say 10 sec down to 1 millisec. Observations of h-f signals from distant transmitters show that such fading is not simultaneous as between (1) horizontally and vertically polarized antennas at the same location; (2) two frequencies spaced 500 cps, or less, in the r-f spectrum; and (3) antennas of the same type spaced geographically by distances ranging down to as little as a few wavelengths at the frequency of the signal. This difference or diversity of fading is taken advantage of in the so-called diversity method of reception.

Frequency diversity, which may be obtained by phase- or frequency-modulating the crystal oscillator of the transmitter at a 500-cps rate or by simultaneous transmission of the same keying on two or more modulating tone frequencies applied to the transmitter, is very effective. Generally speaking, the slower the fading the greater the frequency separation required to provide a worthwhile diversity effect. The method requires the use of only one antenna and receiver but is wasteful of frequency-spectrum space.

Space diversity employs two or three antennas spaced approximately 10 wavelengths, or a compromise distance of 1,000 ft, apart, each antenna supplying signal to a separate h-f receiver. The outputs of the individual receivers are combined or switched in such manner as to ensure the best possible signal-to-noise ratio in the final diversity signal that drives a relay or a tone-keyer stage.

Polarization diversity gives the least improvement and so is used only where some form of frequency diversity is impracticable and where space for antennas is very restricted.

Transmitter diversity[44] employs two h-f transmitters radiating from geographically spaced antennas. A very small frequency difference, of some 90 cps, prevents the

setting up of patterns of r-f addition and cancellation between the two radiations and in the receiver. A single receiver of special design is used. The method is of value in special types of service where receivers and receiving-antenna installations must be small and simple, and where the improved reception, perhaps simultaneously at a number of widely scattered points, justifies the increased cost of transmitting facilities.

Improvement obtainable by diversity reception is such that h-f point-to-point RT services consider it essential. To express the improvement in definite figures, however, is difficult because it depends to such an extent not only on antenna or frequency spacing, and on fading conditions, but also on the signal-to-noise ratio. It now is customary to express the improvement in terms of the increase in transmitter power that would be required to give the same reduction in error count as is produced by diversity reception for a given set of conditions and signal-to-noise ratio.[38] For two-receiver diversity, either frequency or space, the improvement has been variously estimated, observed, or calculated as ranging from 5 to 30 db. A representative figure for practical use is 15 db. It is interesting to note that the improvement, expressed in this manner, is greatest for high values of signal-to-noise ratio and least when signal-to-noise ratios are very low. Addition of a third receiver, in diversity combination, provides a further improvement of perhaps 2 to 8 db. While such a rating in decibels is convenient and is of use in over-all system design, the figure of interest to traffic and technical operating personnel is the reduction in error count. At the very low values of signal-to-noise ratio, when mutilations caused by noise "fills" and by fading "drops" are frequent, a "diversity improvement" of only a few decibels may give a 2 or 3 to 1 reduction in error count.

58. Diversity Receivers, General Characteristics.[45,46] In a major point-to-point receiving station that handles a large number of signals simultaneously, the individual h-f receivers used in diversity combination must be of good design as regards all the conventional characteristics and, furthermore, must be well filtered and shielded to prevent r-f or i-f cross talk between receivers and r-f oscillator radiation onto antenna transmission lines and antennas. With transmission lines having negligible stray pickup and an antenna system well balanced with respect to ground, the r-f transfer from balanced antenna system to any unbalanced system, such as coaxial line or a tuned grid circuit, should be through an inductive coupling provided with an electrostatic shield between windings. Otherwise, the polarization and directional characteristics of a good antenna system may be seriously impaired.

Frequency stability of all r-f and i-f heterodyne oscillators is a major consideration where ultimate i-f or a-f band width of a channel may be only 200 cps or less and where the receivers must operate with a minimum of routine attention. Where the use of fixed-frequency crystal oscillators is impracticable or operationally undesirable because of the need to receive on numerous frequencies, oscillators of well-stabilized design and low temperature coefficient are essential. The latter may be supplemented by automatic frequency control, though the use of AFC, on some types of RT signal and under adverse conditions of noise or interference, often is questionable.

Automatic gain control (AGC) is derived from the rectified and combined outputs of the individual receivers; the voltage thus derived is fed back as a bias to the r-f, and sometimes the i-f, amplifier stages of all receivers (see Fig. 7). In diversity reception, this common AGC has a dual role. It maintains the rectified i-f output signal reasonably constant over a wide range of antenna signal strengths; and because it holds the gain of all receivers the same at any instant, the i-f output signal from any one receiver is proportional to the instantaneous r-f signal strength at its antenna. Thus, the antenna having the best signal-to-noise ratio at any instant will contribute most to the output signal. (Qualification of this generalized statement will be taken up later.)

Limiting may be used to ensure holding the level of the i-f or the rectified output signal constant within closer limits than AGC alone will effect, particularly on fading that is too rapid for the AGC to follow. In the case of on-off keying, any such limiting

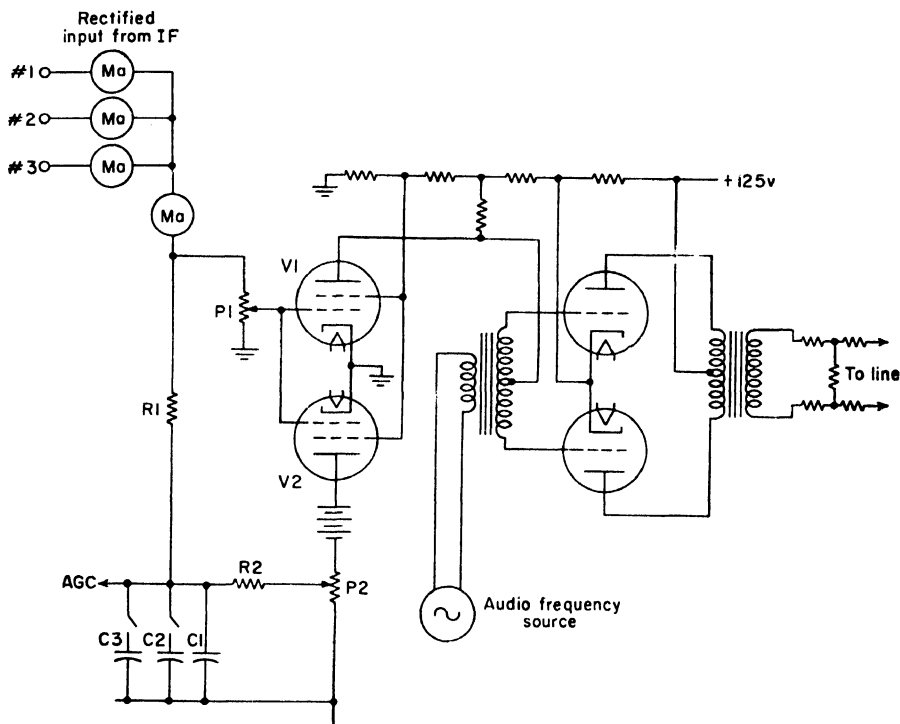
must follow the final selectivity. It customarily appears in the output relay or the tone-keyer circuit (Fig. 7). Since the envelope shape of the keyed signal supposedly contains at most the fifth, and often no more than the third, harmonic of the fundamental keying frequency, the rise and fall are not instantaneous but have appreciable slopes. Therefore, only comparatively small amounts or degrees of limiting may be used if the M/S ratio of a varying signal is to be reproduced with the required fidelity. In the case of FSK, amplitude limiting does not affect the frequency-shift envelope formation of the keyed wave. Limiting therefore may be, and is, used. This makes it possible to design receivers that are far less critical of adjustment on radiotelegraph


FIG. 7. Diversity combining and on-off tone keyer.

signals which are fading badly. This is one of the outstanding reasons for the practical superiority of FSK over on-off keying for h-f services.

Combining or *switching* of the outputs of the individual receivers used in diversity combination is effected in various ways, the object in all cases being to supply as nearly perfect a signal as possible to the output relay or tone-keyer stage. Typical methods are individually dealt with in following sections.

59. Diversity Receivers, On-Off.[45] Historically and technically, the basic combining circuit for two- or three-receiver diversity reception of a-m or on-off keyed signals is shown by the left-hand portion of Fig. 7. In each receiver, the final i-f signal is rectified and filtered. Filtering is necessary to prevent i-f components from the individual receivers from interacting and producing a-f beats in the combined output when the receivers employ separate rather than common oscillators. Where the i-f system is of relatively low frequency, such as 50 kc, and the modulation components may range up to several kc (voice), it is necessary to use well-balanced full-wave rectification so that the filtering may be made as light as possible, each filter

effectively being capacitively loaded by those of the other receivers paralleled with it. The rectified outputs combine in the common load resistor P_1, from which a suitable voltage is picked off to drive the limiter-reverser tube V_1 which, in turn, changes the bias on the push-pull output stage and thereby keys the tone signal derived from the local a-f source. The final output signal thus is an on-off keyed tone of constant frequency and amplitude.

AGC voltage, fed back to the r-f amplifier stages and sometimes to certain i-f stages of the two or three receivers in use, is derived from the total rectified signal output voltage across the common diode load resistor P_1, R_1 with switchable capacitors C_1, C_2, and C_3 providing a choice of time constant to best handle different speeds and types of fading. A threshold or holding bias to prevent the r-f gain and noise from rising too high during pauses in on-off keying is derived through the coupling-reverser tube V_2 and its plate circuit, the value of this threshold voltage being adjustable by P_2. What this circuit does, in effect, is to deliver an AGC voltage which is derived from the signal when signal is present and from the threshold tube V_2 and potentiometer P_2 when there is no signal present.

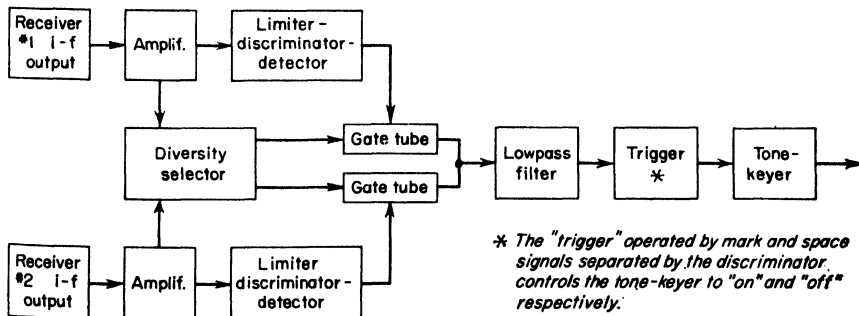
Combining the rectified outputs in a common load resistor, as shown in Fig. 7, provides additional switching action over and above that due to the common AGC on all receivers. It is assumed, here, that the signal rectifiers in the individual i-f units are the usual diodes. The voltage across the common load resistor biases these diodes and tends to cut off all but the one which at the moment has the highest value of signal on it. The result is that the rectified outputs of the individual receivers are not proportional to the respective antenna signal strengths, as was stated above when discussing the common AGC. Instead, this difference is accentuated, the receiver having the strongest signal thus supplying most, or all, of the combined output. With individual receiver gains properly adjusted for equal noise level, this inherent voltage regulation or switching action of the common diode-load circuit ensures that the total rectified output will be supplied mostly or entirely by the receiver having the best signal-to-noise ratio at its antenna.

Signal-to-noise ratio in the rectified signal sometimes may be improved by use of a low-pass filter inserted between the point where the three signals are combined and the common load resistor. This method is effective in cases where the band width of the radio receivers is far greater than required for the maximum keying speed, and so long as noise or interference does not drive the i-f systems or the diodes beyond their linear ranges.

The question of two-receiver vs. three-receiver diversity operation has been answered differently by different organizations. For on-off keying, provision of AGC with the threshold feature, and what little limiting is permissible, sometimes is not sufficient to satisfactorily handle adverse conditions of signal-to-noise ratio and fading. At such times, the use of a third receiver appears to be justified.

60. Diversity Receivers, FSK. As regards the r-f and i-f systems of the individual receivers and the manner of deriving a common AGC voltage, diversity receiving equipment for FSK operation is the same as that already described, in Sec. 59, for on-off keying, the AGC voltage for all receivers being obtained through a time-constant circuit connected across the common diode load resistor (see left-hand portion, only, of Fig. 7).

For FSK operation, the diversity receiving equipment differs in two essential respects from that used for on-off keying. These are (1) large amounts of limiting may be used after the i-f selectivity; and (2) the FSK signal must be converted to the on-off form for combining or switching and for driving the output relay or tone keyer (see Fig. 8).

Limiting is used, following the i-f selectivity but before conversion of the FSK signal to on-off, to maintain the i-f output signal and the converted signal at a constant amplitude regardless of individual fades that diversity and AGC have not completely taken care of. The resultant d-c on-off signal thus has a constant marking value, which permits the use of a rounded or even a sinusoidal keying wave shape


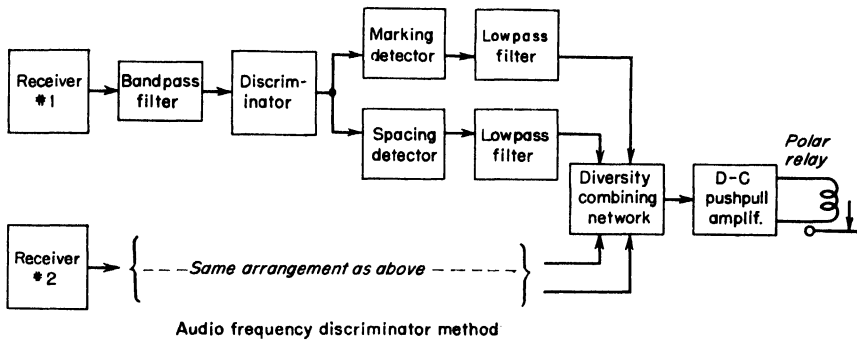


FIG. 8. Receiving methods for frequency-shift keying.

and of setting the operating point, for the following stages and the output relay or tone keyer, at the 50 per cent amplitude level on the rectified keying wave. This ensures that the M/S ratio, in the final output signal from relay or tone keyer, will faithfully reproduce the original keying within close limits regardless of fading.

Conversion of the FSK signal from frequency-shift to on-off is effected by either of the two methods illustrated in Fig. 8 and described below.

Mark and space filters may be used on a signal of the two-frequency-keying type, for which this method is particularly adapted, or on a true FSK signal. In the two-frequency or two-source keying case, the M and S frequencies may have a considerable frequency separation such as the 850 cps used in many applications where standard v-f filter channel spacings were multiples of 170 cps. Whatever the spacing employed, it is preferable to have the filter pass bands centered on the M and S frequencies, respectively, and to have the band widths of each sufficient only for the maximum keying speed to be used. Where the M and S frequencies constitute a single channel, and there are no other channels inserted between them as may be done in tone-channel-multiplex systems, the usual band-pass filters may be replaced by a full-channel-width "roofing" filter and high-pass and low-pass filters for the M and S, respectively. When used on a true FSK signal, the necessary guard band between filters, at the crossover point of their frequency characteristics, imposes a limitation on the minimum usable value of frequency shift. It also is necessary, particularly in the true FSK case, to maintain the central "carrier" frequency of the i-f or a-f signal accurately centered on the crossover frequency between the filters. This may require the use of AFC in the individual receivers, or on common oscillators used to supply the receivers operating in diversity combination. One advantage of the mark-space filter method is that it will hold a steady M or S output for any length of sustained M or S condition on the incoming radio signal.

The so-called *discriminator* method of conversion employs a conventional f-m converter circuit which, for keyed services, may take the form of two resonant i-f circuits tuned to peak at frequencies respectively well above and below the maximum limit M and S frequencies to be received. These two circuits, with their crossing frequency characteristics, supply two detectors or rectifiers designated as the M and the S detectors (see Fig. 8). Permissible values of total frequency shift are limited only by: (1) for minimum shift, by the slope of the discriminator characteristics and the sensitivity of the following detectors; and (2) for maximum shift, by the frequency separation between the resonant or peak frequencies of the two i-f circuits supplying the detectors. A further consideration, however, is the type of coupling from the differential output circuit of the M-S detectors or rectifiers to such following circuits as may be used to further "square up" the rectified signal before it is applied to the output relay or tone keyer. If this coupling is direct—which may involve circuit-design complications—the system is capable of maintaining a sustained M or S output for any such protracted condition of the incoming radio signal. If this coupling is through a capacitor—which simplifies some circuit-design problems—the system will pass the lowest-frequency component of the d-c keying wave but will not maintain steady M or S conditions in the output signal. Some form of mark-restorer, or of space-restorer, circuitry then is required.

Diversity combining or switching, as in the case of on-off equipment, is effected after the signal has been rectified. This eliminates the possibility of r-f or i-f phase-cancellation effects and interreceiver beat frequencies. In the FSK case, however, there are some further considerations. The common AGC, and the voltages to control the gating or switching tubes of Fig. 8, must be derived from the signal after the i-f selectivity but before limiting. The purpose of gate tubes is to provide sharper and more complete diversity switching action than is obtainable with other conventional types of combining circuit.

A low-pass filter, shown in Fig. 8, eliminates undesired modulation components and noise, or M-S beat notes, on frequencies above those required for the maximum keying speed. This filter preferably should be designed to pass the third harmonic of the fundamental keying frequency, as this generally is desirable for consistent maintenance of the proper M/S ratio. However, where keying speeds are low enough not to be appreciably affected by multipath delay, and where the use of limiting and "squaring-up" or "trigger" circuits ahead of the tone keyer permits a sinusoidal keying wave shape at this point, the low-pass filter may be designed to pass only the fundamental of the highest keying frequency to be used.

61. Diversity Receivers, SSB.[46] In a frequency-division tone-channel SSB system, the full benefits of diversity reception can be obtained only by treating each different keying channel as a separate signal and providing it with its own individual, or common-diversity, AGC. This is essential because selective fading makes the individual tone-channel signals fade differently, and therefore an AGC derived from one would not be suitable for use on another unless used in diversity combination. This diversity of fading, as between tone channels, may, however, be used to provide frequency diversity. Whether frequency or space diversity be employed, the common AGC system and combining circuits are basically those already described for on-off and FSK diversity receivers, the method being determined by the mode of keying employed for each telegraph or teleprinter channel.

Each receiver comprises a conventional r-f and i-f system of sufficient band width to pass all required side bands of the SSB signal, and is supplied with its own slow AGC to hold the average signal within reasonable limits and thus prevent overloading. Final selectivity for the individual tone channels is obtained in each receiver by the use of a bank of standard v-f filters or, in special designs, by channel i-f filters at a frequency of some 10 kc.

A typical design provides 16 channels with mid-band frequencies spaced 170 cps, from 425 to 2,975 cps, inclusive. (Note: Other v-f carrier-telegraph systems employ mid-channel spacings of 120 and 150 cps, respectively.) Where one tone channel is to carry the keying of a two- or four-channel TDM aggregate, as is necessary when using present-day designs of automatic-RQ equipment, the band width allotted to this tone channel is a multiple of the basic channel spacing of the system.

On-off keying of a single tone is the simplest application and provides a maximum number of telegraph or teleprinter communication channels for a given number of tone channels. Space diversity must be used, if quality performance is desired.

Two-frequency keying, in which one tone channel is used for mark and another tone channel is used for space—keying on one being the inverse of that on the other—may be employed to provide improved performance similar to that obtainable with true FSK. Early examples employed tones spaced 850 cps apart for M and S.

FSK applied to the carrier tone on each tone channel is the preferred mode of operation.[46] Used with space-diversity reception from two suitably designed receivers and two antennas, this mode provides the maximum in performance and number of communication channels for RT service by FDM over SSB or equivalent facilities.

Frequency diversity may be provided by duplicating each M tone and each S tone, or each FSK channel, on another tone frequency some 500 cps or more removed. This requires twice as much spectrum space or, for a given number of tone channels available, cuts in half the number of communication channels that can be provided.

62. Receiver Selectivity. Final channel selectivity required in the individual receivers used in diversity reception of h-f signals is determined by the speed and mode of keying and the value of total frequency shift in the case of an FSK signal in accordance with keying analyses as given in Secs. 30 and 35. In practice, the optimum band width will be a compromise between that required for high fidelity of keying reproduction and what would be desirable from the viewpoint of minimizing noise and interference. Reasonable compromises, neglecting frequency drift, appear to be as follows.

For on-off keying, the required nominal pass band at, say, -3 db should be six times the highest fundamental keying frequency, a keying speed of 25 dot-cycles per sec, or 50 Bauds, thus requiring a nominal pass band of 150 cps.

For FSK, the required nominal pass band at, say, -3 db can be determined from the tabulation of side-band amplitudes given in Sec. 36, allowing all side bands down to an amplitude of approximately 10 per cent to be passed. It must be remembered that the tabulated values are for a single sinusoidal modulation component and so do not cover third and higher-order harmonic components of the keying wave. The latter may be obtained from the tabulation by assigning suitable values to f (see

Sec. 36). A practical compromise for h-f receiver design purposes is

$$\text{Total nominal band width required} = 2(\Delta F + 1.5f) \quad \text{cps}$$

A flat-topped frequency characteristic, with practically square shoulders, would seem to be the ideal. Such a pass-band characteristic, however, produces an objectionable "overshoot" transient at each M-S and S-M transition of the keying.[47] A somewhat rounded top therefore is preferable.

Skirts of the frequency characteristic, outside the useful pass band, should be as steep as possible or practicable to provide maximum protection against adjacent-channel interference. In practical designs of commercial equipment, the slope of these i-f or over-all selectivity skirts has run as high as 100 or even 200 db per kc (CCIR, Geneva, 1951, Recommendation No. 42 Annex).

Image and other spurious responses, normally arising in heterodyne converters (mixers) or due to overloading by undesired signals of great strength, should be kept below −80 db relative to response to the desired signal. Even greater protection, if economically practicable in the receiver design, is desirable.

REMOTE CONTROL AND SIGNAL TRANSFER

63. General Aspects. Particularly in the fixed point-to-point h-f services, it is necessary to have the so-called central radio office[48] or terminal office located in the business district of a city or close to some major headquarters of operations. The associated h-f transmitting and receiving radio stations often must be located considerable distances from this central control office. In such cases, suitable facilities must be provided for remote keying of the transmitters and for transfer of the received radio signals. If the distance is relatively short, or the number of signals to be handled is relatively small, the simplest and most economical method is the use of d.c. of single or, preferably, plus-and-minus polarity with suitable electromechanical relays. Major centers, however, have their associated radio stations at such distances—now generally within 100 miles—that performance, particularly at high keying speeds, and economy of wire-line or radio-relay facilities dictate the use of standard voice-frequency (tone) carrier-telegraph techniques and equipment. The requisite voice channels are provided over wire-line circuits, or over radio-relay facilities operating in the u-h-f or microwave range.

64. Filter Systems. The basic voice channel over telephone lines or radio-relay facilities has a nominal band width of 3,000 cps though it often extends up to 3,400 or 3,500 cps. This may be divided into two wide-band telegraph channels by the use of a low-pass and a high-pass filter having cutoff frequencies in the neighborhood of 1,500 cps to handle signals of unstable frequency or signals being keyed at high speeds. The more usual arrangement, however, is to employ a bank of band-pass filters to divide the total voice band into a number of channels of widths suitable for the keying speeds to be handled on each tone channel. Typical systems for handling single 60- to 100-wpm printer signals provide 16 or more band-pass channels of 170- or 150- or 120- cps mid-channel spacing as indicated below.

A	B	C
425	525	420
595	675	540
765	825	660
935	975	780
1,105	1,125	900
1,275	1,275	1,020
etc. to 3,145	1,425	etc. to 3,180
	1,575	

A = A.T. & T. Co.
B = Western Union Telegraph Co.
C = CCIT, European, and some United States.

Higher keying speeds, such as two- or four-channel seven-unit TDM, require band widths, and therefore band-pass filters, of greater width. Such filters are designed to pass the equivalent of two, or even as many as five, times the band of a basic channel, being fitted into the over-all plan of channel allocations tabulated above.

Full utilization of high-quality telephone or program circuits, that pass up to some 5,000 or even 7,500 cps, requires the use of special filters. These usually are designed to have relatively wide pass bands to handle high-speed keying such as four-channel TDM. For single-channel speeds, it is customary to utilize two or more standard groups of narrow-band filters by "stacking" one above another in the frequency spectrum. This process of shifting an entire group upward in frequency by, say, 3,000 cps, is a standard technique. At the receiving end of the line, the shifted group is shifted back down to its original frequency range and the individual channels separated out by a bank of standard filters.

Filters at the transmitting end of the circuit need provide only sufficient selectivity to prevent passage of harmonics of the tone carrier frequency and to reduce the amplitude of keying side bands that might fall within the pass band of the adjacent channels.

Filters at the receiving end of the circuit must provide the selectivity required to select the desired channel only and prevent interference from signals on adjacent channels. Such filters may, of course, be used as transmitting filters also.

Optimum performance of filters is obtained only when they are supplied from, and work into, a constant resistance of the value for which the filter is designed. If source or load is of varying or questionable impedance, the filter should be partially isolated from it by insertion of a resistance pad, of proper impedance in both directions, having an attenuation of from 6 to 10 db.

65. Tone Keyers. The carrier tone on each filter channel must be keyed in accordance with the telegraph or teleprinter signal that is to be sent over the channel. On-off keying generally is employed because of its relative simplicity and the system flexibility made possible by its use. While FSK of the channel tones is in wide use on some wire-line systems, and in certain special applications over radio-relay systems, it has not been widely used for remote control and signal transfer in commercial RT systems.

The balanced-modulator type of tone-keyer circuit is illustrated in Fig. 7, where it is driven or keyed by a grid-bias voltage derived from the combined d-c signal out of the diversity receiving equipment. In the case of transmission, where the telegraph keying originates locally in teleprinters or tape transmitters, the latter supply a keyed d-c voltage that swings the grid bias on the balanced-modulator stage from its normal operating or M value to an S value that is well below cutoff for the tubes. The result is that the steady tone signal, from the a-f source of Fig. 7, is respectively amplified and blocked by the push-pull amplifier tubes.

Minimization of keying transients is effected by (1) use of matched tubes to prevent a large unbalanced d-c component in the primary winding of the output transformer, (2) use of maximum permissible tone excitation on the grids at all times to provide a maximum ratio of output tone to residual unbalance transients, and (3) adjustment of final output level by use of an attenuator following the output transformer. An alternative, but less desirable, arrangement is to connect a potentiometer between the two halves of the plate winding of the output transformer and connect the plate supply to the slider on this potentiometer. The latter then is adjusted for minimum keying transients by observing the keyed tone output signal on an oscilloscope.

The output impedance of such a tone keyer at the terminals of the output transformer swings between its nominal value of say 600 ohms on M to a very high value of possibly many thousands of ohms on S. As this constitutes an unsatisfactory termination or source for most filters and lines, an isolating pad of some 6 to 10 db should be permanently associated with the tone keyer.

If the input impedance of the input transformer is high enough for bridging use, a number of such tone-keyer units may be supplied from the same tone source. In a

large installation handling many circuits and signals, this provides both economy and flexibility.

The ring modulator may be used as a tone keyer (see Fig. 9). Diodes may be of the copper-oxide or germanium-crystal types. With such a ring modulator the tone source must supply sufficient voltage and actual power to provide the required output level of keyed tone after a loss of from 6 to 10 db in the ring modulator. If more than one such tone keyer is to be supplied from a common tone source, the latter must be of sufficiently low impedance to supply the several loads with negligible voltage drop or interaction.

66. Tone Levels. The steady mark output from all tone-keyer units, in any one system or installation, should be adjusted to a standard level. This facilitates monitoring and trouble shooting, provides flexibility of operations, minimizes cross talk within or between filter groups, and reduces the possibility of accidental overloading and consequent intermodulation in telephone-line repeaters or radio-relay channels. The standard level, in a 600-ohm circuit, often is established at 6 mw at the monitoring points. It may, however, be considerably lower in some systems, particularly at the input to the telephone line or radio-relay channel, exact values being dependent upon, and specified for, each case.
FIG. 9. Ring-modulator tone keyer.

67. Tone-signal Converters. For keying control of the usual RT transmitter, or for actuation of telegraph recorders and teleprinters, the keyed tone signal received over a telephone line or radio-relay channel must be amplified and then converted to an on-off d-c signal of single, or of plus-and-minus, polarity. This is accomplished in a so-called tone-signal converter, which consists of a conventional v-f amplifier of suitable frequency range and gain followed by some form of rectifier. Use of a full-wave rectifier will double the ripple frequency on the rectified signal and thus simplify the problem of designing smoothing circuits or a low-pass filter that will smooth out the ripple with a minimum effect on the keying wave shape. It often is desirable or necessary to maintain the M-S and S-M transitional operating point at a fixed level on the wave shape of the rectified signal regardless of moderate variations in the level of the received tone signal. This is of particular importance where the keying envelope shape of the tone signal received over a narrow filter channel approaches sinusoidal rather than rectangular shape. In such applications, the tone-signal converter is designed with special circuits which hold the transitional operating point at the 50 per cent level within quite close limits over a considerable range of tone-signal input level. This ensures the correct M/S ratio in the rectified output signal regardless of moderate variations in the level of the tone signal received over the filter channel.

TERMINAL-OFFICE EQUIPMENT

68. Morse Equipment. In mechanized or "automatic" Morse operation, a keyboard *perforator* (Fig. 3) is used by the transmitting operator to prepare a perforated tape (Fig. 10) which then is run through a tape transmitter to produce the keyed electrical signal for controlling the radio transmitter. The perforated tape, as illus-

trated in Fig. 10, contains a row of center or feed holes which engage with the teeth of a star wheel, in the tape transmitter, to feed the tape through continuously at a constant speed which is adjustable over a wide range to give traffic keying speeds of from 10 or 15 to several hundred wpm.
Fig. 10. Morse perforator tape.

The tape transmitter consists essentially of two cam-operated sensing pins or rods that alternately come up against the tape at every point where a perforation might exist, that is, opposite each center hole. If there is a perforation, the sensing pin goes through and thus causes an electrical contact to be closed by a lever or other mechanism associated with the lower end of the sensing pin. If no perforation exists, the sensing pin is stopped by the tough paper tape and the electrical contact is prevented from closing. The two sensing pins which line up with the two rows of perforations in the tape control the "make" or "mark" contacts and the "break" or "space" contacts. The pins alternate in their up-and-down movement against or through the tape and are sufficiently offset in the direction of travel of the tape to produce a Morse dot signal when upper-row and lower-row perforations are opposite the same center hole, and to produce a Morse dash signal when the upper-row and lower-row perforations are opposite adjacent center holes. (In Fig. 10, read the perforations from left to right.)
Fig. 11. Ink recorder. Paper tape and tape guide not shown.

Reception, particularly at the higher speeds, is effected by recording the incoming Morse signal on an *ink recorder*, or *undulator*, as shown in Fig. 11. This type consists of a small coil of many turns of very fine wire suspended in a strong radial magnetic field supplied by an electromagnet, the magnetic circuit of the latter consisting of the central core, the iron shell and cover plate, and the air gap in which the small signal coil is suspended. D-c pulses, of the amplified and rectified Morse signal, are sent through the signal coil of the recorder. Marking current causes the suspended coil to move upward and drive the pen arm against the upper stop. Spacing

T H I S I S A S A M P L E
Fig. 12. Sample of Morse ink-recorder tape.

current—zero or of opposite polarity from marking—causes the coil to be returned to the lower stop by action of the spring and the coil suspension, or by the reversed polarity, as the case may be. Mark and space (positive and negative) polarity currents are employed, instead of single polarity on-off, to improve the action of the device at high speeds; such double-current signals are obtained from a pole-changing relay or from a special design of tone-signal converter that gives a rectified output of opposite polarity for mark and space. Speeds attainable run to several hundred wpm.

The tape record is illustrated in Fig. 12.

Printing telegraph machines which operate directly from a Morse-code signal are used on some RT networks, notably the British.

69. Teleprinter Equipment. In international RT services printing telegraph equipment commonly is referred to as teleprinter equipment or by specific trade names as "Teletypewriter." As pointed out in Sec. 16 of this chapter, equipment in general and most widespread use on RT circuits is the standard five-unit start/stop equipment of wire-line services. The code is shown in Fig. 2, a typical keyboard in Fig. 3, and operating speeds in the tabulation of Fig. 4 (see also Chap. 27, Secs. 35, 43).

Cooperation between start/stop teleprinter machines or networks requires that they utilize (1) the same basic code (five- or six-unit); (2) the same code-character assignments; and (3) the same time duration, in milliseconds, of the start and the five code-selecting unit intervals. The stop interval, following the last code-selecting interval, may be of unit-element or any greater duration. This is because the standard receiving mechanism comes to rest at the end of each code combination received after approximately 6.5 unit intervals. Therefore, the duration of the stop interval in the transmitted signal may be anything greater than a nominal minimum of unity. This explains the various total unit intervals per character of 7.0 or 7.42 or 7.5 units tabulated in Fig. 4.

NOTE: An exception to the above is certain types of start/stop signal regenerator which operate on a 7.0-unit cycle, instead of 6.5, and therefore require a transmitted stop interval of greater than 1.0 to supply sufficient margin for operation.

The basic machines are:

Send-receive keyboard printer
Keyboard tape perforator
Tape transmitter-distributor
Receiving printer—tape or page
Reperforator—typing or nontyping

The send-receive keyboard printer is commonly used in customer-to-customer services such as the TEX Overseas Teleprinter Exchange Service, on customer tie lines for filing and delivery of radiotelegrams, and on domestic wire-line circuits to inland points. Other commercial RT services generally employ tape transmission, requiring the use of keyboard perforators and tape transmitter-distributors, and tape relay requiring typing reperforators. Receiving printers generally are of the so-called page type which prints the received message line after line just as an office typewriter does. This eliminates the necessity of pasting tape onto a message blank, as must be done when tape printers are used.

Perforated tape for five-unit teleprinter services has a continuous row of feed holes and five rows of perforations corresponding to the five columns of Fig. 2, where circles indicate tape perforations. The tape transmitter steps this tape along, one feed hole or character at a time. While the tape is at rest, for one feed hole, five sensing pins come up against the tape. Those finding perforations pass through and cause electrical contacts within the tape transmitter to close and provide the M condition for these code elements. Where a sensing pin finds no perforation in the tape, its electrical contact assumes the S condition. In some types of equipment, such as synchronous multiplex equipment, reperforators, etc., the M and S voltages from these five sets of contacts are presented simultaneously and set up the desired combination for further processing. In start/stop systems, however, these five elements must be distributed in time to follow one another in the proper sequence and duration, and they must be preceded by a unit-length start interval and followed by a stop interval of specified duration. These functions are performed by a distributor associated with the tape transmitter proper, the resulting signal for one code combination, in a typical system, having a total duration of $22 + 5(22) + 31 = 163$ millisec.

70. Multiplex Equipment. The TDM mode of operation has been briefly described in Sec. 23. For teleprinter service employing equal-length codes such as the five-, or six-, or seven-unit synchronous or the five-unit start/stop of 7.0 total units there are two basic TDM modes. These are the sequential and the interleaved.

Sequential. The sequential system transmits an entire code combination (one letter, character, or operation) for one channel before starting transmission of a code combination on another channel. This is illustrated below.

Channel I	T H I S
Channel II	W H E N
Channel III	J U N E
Channel IV	F O U R
Aggregate	TWJFHHUOIENUSNER

For the four-channel case illustrated, the time duration of a single-channel unit element is divided into four equal parts. These ¼-length intervals are the unit elements of the four-channel aggregate signal. Thus, four characters—one on each channel—are transmitted in the time normally allotted to the transmission of one character in a single-channel system. At the receiving terminal, a synchronous distributor breaks down the aggregate signal and distributes characters to the respective channel printers.

Mode	Sequence
1	A C B D A C B D A C B D
2	A B A B A B
3	A B A B A B A B A B A B A B C-1 C-2 C-3 C-4 C-5 C-6 C-7 D-1 D-2 D-3 D-4 D-5 D-6 D-7
4	A-1 A-2 A-3 A-4 A-5 A-6 A-7 B-1 B-2 B-3 B-4 B-5 B-6 B-7 C-1 C-2 C-3 C-4 C-5 C-6 C-7 D-1 D-2 D-3 D-4 D-5 D-6 D-7
5	C-1 C-2 C-3 C-4 C-5 C-6 C-7 D-1 D-2 D-3 D-4 D-5 D-6 D-7

FIG. 13. Multiplex channeling modes.

Typical equipment now used on short-wave RT services employs a six-unit code instead of five-unit and provides channel converters to convert from five-unit start/stop (7.42-unit) to six-unit synchronous and, at the receiving end, from six-unit synchronous back to five-unit start/stop (7.42-unit). This permits the use of standard start/stop teleprinter equipment in the terminal offices and interconnection with existing wire-line systems.

Interleaved. The interleaved system also divides each single-channel unit element into shorter aggregate-signal unit elements corresponding in number to the number of channels desired. In a four-channel system, the first, second, third, and fourth quarters of the subdivided single-channel unit element are allocated to the first, second, third, and fourth time-division channels, respectively. Designating these as channels A, B, C, and D, various modes of use are illustrated in Fig. 13.

Channeling. Mode 2 of Fig. 13 is the simplest case, which is that of a two-channel interleaved aggregate. Mode 1 is a four-channel aggregate consisting of two interleaved two-channel aggregates AB and CD.

It should be pointed out that the interleaved mode of TDM is not limited to the use of equal-length teleprinter codes, as is the sequential mode, but permits the use of unequal-length codes, such as Morse, and of different codes on the individual channels.

Mode 3, of Fig. 13, is a four-channel aggregate consisting of a two-channel interleaved aggregate AB interleaved with a two-channel sequential aggregate CD. Mode 4 is a four-channel aggregate formed by interleaving two two-channel sequential aggregates AB and CD.

The sequential two-channel aggregate or subaggregates of Fig. 13 are known as *diplex pairs* and, in the seven-unit form shown, are utilized to handle seven-unit pro-

tected code channels in pairs as required by present designs of Automatic-RQ equipment.[10] The interleaved two- or four-channel subaggregates, or aggregates, may be used for five-unit start/stop (7.0-unit) channels.

Earlier designs of TDM equipment employed rotating commutators with stationary brushes to provide interleaving, and segmented rings on stationary faceplates with rotating brush arms to provide sequential channeling. While such electromechanical equipment still is in use, later designs utilize electronic circuits and techniques to perform the functions and modes of channeling described.

Synchronization. This is a major feature of all TDM systems. The speeds of transmitting and receiving terminals are controlled by frequency standards, such as electrically driven forks, having an accuracy and stability on the order of 1 part in 100,000. In addition, the receiving terminal must be equipped with circuits that automatically correct the phase of the receiving distributors to hold them in exact synchronism and phase with the aggregate keying of the incoming multiplex signal.

Individual channel signals from tape transmitters or from keyboard printers must be synchronized and phased with the transmitting terminal to which they go. The tape transmitter may have its start-up, on each code combination transmitted, controlled by the multiplex terminal. (This is termed *relaxation control.*) Instead, suitably designed converters or adaptors, associated with the multiplex terminal, may be used to accept a nonsynchronized signal and convert it to a properly synchronized and phased signal for presentation to one channel of the multiplex system.

Speeds. The question of speeds of the multiplex equipment and of associated start/stop equipment has not as yet been fully resolved and standardized. Typical systems require either (1) that the multiplex equipment run at a synchronous speed some 2 per cent greater than the operation-per-minute speed of the printer signals supplied to it, or (2) that the tape transmitters, relaxation-controlled by the multiplex terminal, must have a free-running speed some 1 or 2 per cent greater than the synchronous speed of the multiplex equipment.

Receiving printers used on the individual channel signals from the multiplex receiving terminal generally are standard five-unit start/stop machines; or, where a channel must be extended into a domestic wire-line system, a typing reperforator often is used and the tape is then fed through a suitable tape transmitter closely associated with the reperforator. Through the medium of tape storage this arrangement makes it possible to interconnect synchronous multiplex and start/stop channels that operate at different speeds or that use a different total number of unit elements per code combination, such as 5 or 7.0 or 7.42.

71. Automatic-RQ Equipment. The Automatic-RQ mode of operation[10] has been briefly described in Sec. 21. Equipment in use on commercial circuits between
FIG. 14. Sequential diplex time-interval assignments.

many countries of the world is designed to use the seven-unit constant-ratio protected code[6] for detection of mutilated code combinations (see also Sec. 5). Such ARQ channels are arranged in so-called diplex sequential pairs, according to mode 5 of Fig. 13, two such diplex pairs being interleaved, as in mode 4 of Fig. 13, for four-channel multiplex operation with ARQ protection on all channels.

The 14 time intervals of one sequential diplex pair are assigned to the two channels in the manner shown in Fig. 14, the total time duration being that of one code combination, or character, on a single-channel teleprinter. This is nominally $7 \times 20 = 140$ millisec in the European and international system, and $7 \times 22 = 154$

millisec in the United States system of teleprinter operation. (Actual values differ somewhat from these nominal values.) It will be noted that channel A utilizes diplex elements or time intervals 1 to 7, inclusive, for signaling and elements 8 to 14, inclusive, for local control functions required by the synchronous system and the Automatic-RQ equipment. Similarly, channel B utilizes time intervals 8 to 14, inclusive, for signaling and 1 to 7, inclusive, for controls.

With regard to local controls, typical equipment utilizes the time duration of elements 13 to 14 for detecting a mutilated seven-unit code combination, received over channel A, and for initiation of the automatic request for repetition; similarly elements 6 to 7 are used for channel B mutilation detection.
FIG. 15. Automatic-RQ phasing for circuit-transmission time of seven diplex unit elements, and sequence for single mutilation and RQ.

Designs of ARQ equipment presently in use, or under development, range from the basically mechanical to the basically electronic. However, since all must be compatible, all perform the same basic functions. Essentially, these functions are:

1. Synchronism and phasing
2. Code conversion
3. Storage
4. Detection of mutilations
5. Automatic request and repetition

1. *Synchronism and Phasing.* As in any synchronous TDM system, maintenance of exact synchronism and proper phasing is essential. This is effected in the associated multiplex equipment or in the combined MUX-ARQ terminal where the two are designed as a single assembly. In the ARQ case there is an additional phasing requirement. This will best be understood by reference to Fig. 15, which shows a seven-unit code combination on channel A transmitted from Station X and mutilated in the radio circuit before being received at Station Y; detection of the mutilation; and automatic transmission of the RQ signal on channel A from Station Y back to Station X, where the requested repetition will be supplied from storage.

In the simple case depicted in Fig. 15, the total one-way time of transmission over the circuit is equal to the duration of seven diplex elements. Therefore, the receiving (R) and transmitting (T) portions of the equipment at a given station are in phase as

shown. For other values of time of transmission over the circuit—radio and connecting wire lines, etc.—the phase relationship between the R and T sections at the Slave Station Y may have to be adjusted so that the end of an A-channel code combination in the R section does not coincide with the 13-to-14, mutilation-detecting interval of the T section at either station.

Since the phase relationship so established must be maintained, it is essential that all synchronous portions of the T and R equipment at both stations be controlled from a single frequency standard. This latter is located at the Master Station X, where it directly controls the T portion of the local terminal. At the Slave Station Y, the R portion of the terminal automatically keeps itself synchronized with the incoming signal and, in addition, supplies a controlled and phased slave standard frequency to drive the T portion of the slave terminal. In this way the signal received back at R of the Master Station X is maintained in synchronism with, and in proper phase relationship to, the master frequency standard at Station X.

2. *Code Conversion.* As indicated by Figs. 14 and 15, the entire ARQ system is based on use of a constant-ratio protected code. This is the code in which all intelligence is conveyed over the actual radio circuit. However, at the terminal stations or offices, it is desirable to employ standard five-unit start/stop perforators, receiving teleprinters, reperforators, etc. (except for special seven-unit monitor printers used in locating troubles). Therefore, it is necessary to convert from five-unit start/stop code to seven-unit synchronous, and vice versa (for codes, see Fig. 2).

Suitable code converters form a part of the transmitting and the receiving ARQ equipment at each terminal office. These converters may be of various kinds, typical equipment employing a bank of multicontact relays. Other methods of obtaining the required conversion are based on the use of matrix electrical networks or on the use of mechanical selection similar to that employed in standard teleprinter equipment. Code-combination assignments of the ARQ seven-unit code, as given in Fig. 2, have been chosen to facilitate conversion to and from the five-unit code in a particular design of relay-type converter.

3. *Storage.* A sufficient number of code combinations (characters) must be stored at the transmitting terminal where they originate to make available the requested repetition following receipt of the RQ signal after a total delay such as indicated in Fig. 15. The total time of transmission over the radio circuit and its associated wire lines, plus time consumed in equipment functioning, is adequately taken care of by storage of the last three code combinations transmitted. As each code combination of the message is transmitted from the ARQ terminal, one is wiped out from storage and a new one is admitted from the tape transmitter associated with that channel. Thus continuous transmission is provided except when a repetition is requested.

4. *Detection of Mutilations.* In transmission over the radio circuit, a seven-unit code combination may have its proper 3:4 ratio of M/S elements changed by fading, noise, or interference. In the multiplex-ARQ equipment, regeneration of unit intervals provides a signal in which there can exist only a full integral number of M and of S unit elements. A mutilation will therefore result in M/S ratios such as 2:5, 1:6, 4:3, 5:2, or 6:1. Such deviations from the proper 3:4 ratio can readily be detected by a Wheatstone-bridge circuit in which the net resistance in one arm is controlled by a group of signal-operated relays associated with the seven individual unit elements. Balance or imbalance of the bridge—caused by receipt of a valid 3:4 combination or of a mutilation, respectively—may operate another relay which provides the required circuit, polarity, or pulse to control the functioning or blocking of the printing function and, in the latter case, to cause the request for a repetition to be initiated.

Transposing mutilations, in which both an M and an S element are changed within one code combination, result in valid 3:4 combinations other than the one transmitted. These are not detectable as mutilations. Fortunately, the relative frequency of occurrence of such undetectable transpositions is small.[49]

5. *Automatic Request and Repetition.* Detection and registering of the receipt of a mutilated code combination, as described under (4) above, initiates a sequence of functions as follows:

1. At the local (receiving) office Y:
   a. Prevents printing or other functioning of the receiving printer or reperforator by disabling the circuit to it
   b. Stops outbound transmission on that channel by stopping the tape transmitter
   c. Sends out the RQ signal (see Fig. 15)
   d. Resumes outgoing transmission
2. At the distant (transmitting or originating) office X:
   a. Performs no printing or other function on the receiving printer or reperforator, because of the special code combination for the RQ signal (see Fig. 2)
   b. Stops outbound transmission on that channel
   c. Requests and obtains repetition of the mutilated code combination from storage
   d. Resumes normal outbound transmission, with the code combination immediately following the one for which a repetition had been requested
3. At the local (receiving) office Y:
   a. Prints the character, or performs the operation, called for by the repeated code combination if received unmutilated
   b. Resumes normal inbound reception

The case described is the simplest one in which a single mutilation occurs on the circuit in one direction only. More complex cases are ones such as mutilation of two or more consecutive code combinations, mutilations in both directions at the same or nearly the same time, and mutilation of the RQ signal itself. These various possibilities are provided against in the design of the ARQ equipment.

CHAPTER 25

ELECTRONICS IN AVIATION

By S. B. Poritzky[1]

The tremendous growth of aviation has been inexorably tied to the rapid strides made in the art and science of electronics. Faster and better aircraft have spurred and demanded equally startling advances in electronic equipment. Powerful and complex manned aircraft demand an eye faster than the human eye and response faster than human response to control and use them efficiently. The need for simultaneous operation of many slow and very fast aircraft within a specific geographical area and the efficient and safe handling of these aircraft with respect to each other involve control processes beyond the capabilities of human beings alone. Aircraft are deployed to seek out and destroy an enemy far beyond human sight and traveling so fast and in such intricate maneuvers as to require more than human computation to seek him out. Pilotless aircraft and missiles are used to perform tasks which previously challenged the pilot, in an attempt to reach out tremendous distances and descend on remote targets, meanwhile performing protective maneuvers to elude enemy weapons. In each of these endeavors and the varied others to which the products of aviation are assigned, electronics provides the brains, eyes, ears, and the capability of control. During this phenomenal growth, electronics has graduated from its rudimentary role of providing merely simple communications and entered virtually every phase of aviation.

THE ROLE OF ELECTRONICS

The contributions of electronic equipment in the operation and control of modern aircraft may be subdivided into several categories:

1. The sensors, computers, controls, and displays used in the actual operation of aircraft
2. Devices which are not directly concerned with the actual flying of the aircraft but are tools in the performance of the aircraft mission
3. The communications devices which link the aircraft to other aircraft and to ground facilities
4. The navigation aids which serve as the road signs and highway white lines to aircraft, providing three-dimensional track guidance to the desired objective
5. The traffic-control facilities which enable ground personnel to assure the safe and expeditious movement of many aircraft operating in close proximity to each other

Two yardsticks will help judge the role of electronics in aviation. The electronic equipment installed on the latest civil air carrier aircraft costs more than the full price of a DC-3 aircraft when new. The number of aircraft arrivals and departures at airports having CAA control towers in the United States and its territories in 1946 was slightly over 4 million operations. In 1957, it was more than 16 million operations. In 1960 it is estimated that there will be 22 million such operations.

1. Electronics in Military Aviation. Many of the electronic devices and aids found on modern aircraft have evolved directly from the surge of development of military devices during and since the Second World War. The military designer, searching for the last bit of aircraft performance to achieve a superior weapon, must make heavy demands on electronic devices. In a military aircraft traveling at tremendous speed, in which the pilot must perform many functions, all manner of aids are required to relieve the pilot of routine jobs which machines can do, to free him for his basic

[1] Air Transport Association of America, Washington, D.C.

decision-making responsibility. In addition to the functions of communications, navigation, and traffic control, there must be aids to simplify the flying of the aircraft and to perfect the jobs of fire control, electronic identification, countermeasures, and so on. Although many of the specific problems of the military aircraft are similar in nature to those encountered in civil operations, they are almost always aggravated by the operational need for ever-greater accuracy, greater load capacity, and the capability of operating with less direct and detailed control from the pilot or operator than might be required in a civil situation.

Along with these more stringent requirements go the handicaps which require military equipment to operate over greater extremes of temperature, altitude, shock, and vibration, along with the tremendous handicap that each pound of electronics and each cubic inch of volume used may rob from an aircraft performance which might save the crew's lives.

Development of military electronics must, by its nature, always be in a hurry. In a continuing race for weapons superiority, electronic systems as well as aircraft constantly face the imminence of obsolescence perhaps even before the equipment comes off the production line. Particularly in times of emergency military electronic equipment often cannot be given the long and thorough tests which might be desirable to assure a known-reliable operating system. Electronics in military aviation must frequently take the lead in the exploration of new, untried techniques not only of circuitry but also of operational systems.

In spite of the major differences between the applications of electronics in military and civil aviation, the basic principles of equipment in use are very similar. Although certain special devices, such as electronic countermeasures and fire-control systems, are unique to military operations, the majority of devices which fall into the five categories outlined above perform essentially similar functions in civil and military aircraft. Thus, in surveying the field of aviation electronics, it is appropriate to discuss primarily the many systems and equipments which serve the mutual needs of all aviation.

The basic operational requirements for an aircraft are, first, to travel safely from point *A* to point *B* without interfering with other aircraft performing similar or dissimilar missions and, second, to perform its mission, whether to deliver passengers, cargo, or bombs, to undertake reconnaissance, or to attack another aircraft. The five categories of tools, the sensors, the tools required for the mission, the communications, navigation, and traffic control, are all involved in any aircraft flight. Only the degree and extent of use of the various tools are controlled by the type of aircraft and the type of mission to be performed.

2. Flying the Airplane. In the basic function of flying the aircraft electronics, electromechanics, and the science of mechanics merge to simplify the pilot's job.

Early aircraft, and even some modern small aircraft, not fitted with sophisticated instruments and automatic aids, have employed the senses of the pilot as the basic source of information in flying the airplane.

Several steps are involved in manual operation of an aircraft. The first of these is the "selector" function in which the pilot utilizes his mental processes to decide his destination, route, and flight altitude. Next is the "sensor" function in which the pilot employs his sight, hearing, touch, and balance as sensors to detect deviations from his route as well as such references as altitude, attitude, wind speed, and resultant drift. The "sensor" and "selector" functions are used alternately, since the information developed by the "sensors" usually requires action or decisions to be made by the "selector" function. After selection and sensing, the next step is to convert the decision to act into action. This mechanism of conversion constitutes the "coupler" which converts the sensed deviations and the resultant selected actions into the motor skills of the pilot's hands and feet; thus, the hands and feet serve as the "actuators" to control the rudder pedals and the "stick," which in turn alter the position or path of the aircraft into the selected condition. The fact that the aircraft responds to this chain of selection-sensing-coupling-control and actuation, in effect, tells the

pilot that the aircraft is behaving and proceeding as he wishes. In this fashion, the aircraft proceeds until a new decision is made by the pilot or until his senses tell him that a new decision is required. This chain of events represents a crude form of servomechanism with the human being doing both the sensing of error (deviation from a desired flight path) and the necessary proportional correction or actuation (the application of a command response to an error signal) to restore the aircraft to a desired flight path.

When an aircraft is surrounded by impenetrable fog, the pilot's senses alone are inadequate.

In modern, highly instrumented aircraft, the basic sequence of events described above still exists, but except in the smallest and lightest of aircraft, the methods by which the several acts are carried out are different. A number of electronic and electromechanical aids are available to simplify and improve the control of the aircraft.

3. Substitutes for the Senses. When the weather is bad or when the performance of the aircraft is very high, the pilot can no longer depend upon his senses alone to guide the aircraft. A number of substitutes for the senses have been developed and are in use. Aircraft-altitude information is provided by a simple aneroid barometer calibrated in the altitude equivalent to atmospheric pressure. Air speed, the speed with which the aircraft is moving with respect to the air mass, is obtained by measuring differential air pressures exerted on the aircraft. These instruments and the usual engine instruments in conventional propeller aircraft are primarily mechanical in nature. A more complex sense substitute is a device through which the pilot can be provided with a visual indication of the attitude of his aircraft relative to the horizon. When the weather is good, the alignment of the wings to the horizon serves to provide this information, but this datum is not available when the horizon is not visible. As a substitute for this all-important horizon line, the pilot utilizes a gyroscopic instrument known as an artificial horizon. Although the artificial-horizon instrument is electromechanical, rather than electronic, different applications of the same principle will be met in ensuing portions of this chapter, so that a brief description of the artificial horizon and its major element, the gyroscope, is in order.

4. The Gyroscope. A gyroscope is a spinning wheel mounted in such a way that it can assume any position in space. As shown in Fig. 1, the wheel or rotor is suspended in three sets of gimbals. The rotor spinning around the axis XX is free to turn on that axis on bearings. The gimbal supporting the rotor is free to turn about axis YY on pivots in the outer gimbal. The outer gimbal is free to turn about the axis ZZ on pivots in this portion; thus, the wheel or rotor is free to spin in three degrees of freedom. However, the wheel does not become a gyroscope or exhibit the properties in which we are interested until the wheel spins.

Fig. 1. Elements of a gyroscope.

When the wheel spins, its axis of rotation tends to remain in a fixed direction in space. The wheel resists any force which attempts to change the direction of its axis. Since the axis is at right angles to the plane of rotation of the rotor wheel, the wheel resists any change of its plane. This gyroscopic "rigidity" is maintained with respect to space and not with respect to the earth.

Although the spinning-wheel gyroscope will resist a change of direction of its spin axis, it will move in response to such a force or pressure. This movement is not in

direct response to the force, but the gyro axis will be displaced in a direction at right angles to the applied force, rather than in the direction of the applied force, and in such a way as to tend to cause the direction of rotation of the rotor to assume the direction of the torque resulting from the applied force. For example, if a force is applied in an arc about the axis *YY*, the force is opposed by the resistance of the gyroscopic inertia which prevents the rotor from being displaced about the axis *YY*. If the rotor is spinning clockwise, the force applied about the axis *YY* will tend to cause precession 90 deg ahead in the direction of rotation. Thus, application of the force about the *YY* axis will cause a rotor turn above the *ZZ* axis, and this is a useful phenomenon.

These two properties are basic and vital to the use of the gyroscope as an instrument of flight. Gyroscopic inertia or "rigidity" establishes a reference in space which is free of effect from its supporting body. The method of *precession* described becomes useful in referencing the gyroscope to the earth rather than to its position in space. If a gyroscope is placed anywhere on the earth with its starting position such that the spin axis is horizontal and the gyro is observed from a point in space, the spin axis will remain fixed. Since an observer standing on the earth is, however, subject to the rotation of the earth, the gyro will appear to tilt gradually or drift from the horizontal position. At the end of 6 hr, when the earth has turned one quarter of a turn, the spin axis has appeared to tilt 90 deg and is now in a vertical position. After 12 hr the spin axis is again horizontal but pointing in an opposite direction from the starting position. This phenomenon in a free-spinning wheel or gyroscope is known as *apparent drift*. The spinning wheel will also be subject to friction and slight unbalances and these will also produce forces resulting in gyroscope drift. Since the intention is to provide a wheel which maintains its position with respect to the surface of the earth, corrections must be made for the friction and unbalance and the effect of the apparent drift due to the rotation of the earth.

5. Artificial-horizon Indicator. In this gyroscopic instrument a force to return the spin axis to its normal horizontal position is provided by a mass coupled mechanically to the gyro housing. Gravity controls the erecting mass so that, when the gyro is in its normal horizontal position, the torques about its axis are equal and no force is exerted to precess the gyro. When the gyro drifts from its horizontal position, torque is applied to the gyroscope to cause precession. This precession erects the spin axis of the gyro, and because of the mechanical coupling between the gyro and the mass, the mass is brought back into gravity equilibrium.
Fig. 2. Gyro horizon indicator.

If the spinning-wheel gyro is housed in a case but given three degrees of freedom with respect to the case and thus with respect to the aircraft, the aircraft and instrument case will move with respect to the gyro when the aircraft attitude changes about either the roll or pitch axis. By providing suitable markings on the gyro and on the instrument-case window through which the gyro is seen, an artificial-horizon line is attained, as shown in Fig. 2. If a horizon-equivalent line is shown on the gyro itself, and a miniature airplane is superimposed on it but fastened to the instrument case (thus representing the aircraft), pitch motion "up" will raise the miniature aircraft "up" above the horizon line, which is maintained steady by the gyro. Similarly, if the aircraft rolls to the right, the right wing of the miniature airplane on the instrument case will roll downward to the right with respect to the horizon line.

6. Gyroscopic Compass (Foucault's Gyroscope). An application of the gyroscope quite similar to the artificial horizon is that of the gyroscopic compass. Here, the

rapidly rotating wheel is kept horizontal by means of a pendulum bob attached to the spin axis. Since the earth is spinning on an axis determined by the geographic north and south poles and the spin axis of a gyroscope is subject to the action of the pendulum, the spin axis oscillates about a meridian with the torque of restitution to the horizontal being maximum at the equator and falling off as the cosine of the latitude, going to zero at the poles. Because of the damping caused by friction and other sources in the gyroscope, the gyro spin axis ultimately comes to rest pointing toward the true geographic north. The gyroscopic compass is independent of magnetic flux and can be used in areas where magnetic disturbances do not permit the use of a magnetic compass.

7. Magnetically Slaved Gyro Compass. Since the magnetic pole, and thus the magnetic meridian, do not align with the geographic poles and the geographic meridian, the directional gyro must be provided with a magnetic sense if it is desired to use the magnetic north as the aircraft-heading reference. For this type of application, the gyro must be slaved to the earth's magnetic field. To accomplish this, the sensing elements for the magnetic lines of force are related to the gyroscope output signal. The signals from the gyro will now be used in a direction indicator only after they are modified by the output of a sensing detector of the magnetic lines of force. The gyro output and the magnetic flux detector are electrically combined in a synchro system and the drift of the gyroscope is controlled so that the gyro spin axis maintains magnetic north as its reference position.

It may be seen that the gyroscope in several forms is an extremely useful tool in substituting for the senses of the pilot. The artificial horizon and the gyrocompass described above serve only as examples of many applications of the gyroscope. The gyrocompass, and particularly the gyrocompass slaved to the magnetic lines of force, constitutes a basic aircraft master direction indicator and has important application in the transition to automatic flight.

8. Sensing and Repeating of Information. The pilot who "flew by the seat of his pants" utilized his physical senses to detect deviation from his route, attitude references, and the effects of his manipulation of the controls. As the process of flight becomes more complex and we begin to depend on aids other than the pilot's senses, the output from such things as gyroscopes and navigation devices can no longer be observed and acted on directly—particularly as the transition to automatic flight begins.

9. Synchro Systems. The need for the display of information at locations other than those where the information is generated, such as the position of control surfaces, gyro orientation, etc., as well as a requirement to exert a force at a distance which may be proportional to but much larger than the controlling force, has resulted in wide usage of synchro systems and servomechanisms in aircraft.

The simplest form of synchro system used in modern aircraft is the transmitter-receiver (repeater) system. In this synchro system, the two units are electrically identical. The transmitter is turned by the original data source and the receiver follows to indicate corresponding angular data at a remote point, as shown in Fig. 3. The voltages across the wires X, Y, Z[1] are single-phase voltages derived by straight transformer coupling from the field produced by the rotor. In a consideration of the potentials existing between the three line terminals of the synchro system the distribution of voltages across the X, Y, Z terminals is illustrated in Fig. 3. The simple transmitter-receiver synchro system operates on the basis of exact alignment between transmitter and receiver rotor-shaft positions. Under the condition of alignment, the line current flowing through the rotor coils of the transmitter and the receiver units induces voltages in the stator coils to these units which are equal and opposite, resulting in a theoretical condition of zero current in the X, Y, Z wires at balance.

When the transmitter shaft is displaced relative to the receiver shaft, the X, Y, Z voltages from the transmitter are no longer equal to those induced in the receiver stator. As a result, relatively large circulating currents flow in the wires X, Y, Z.

[1] Standard ARINC Synchro System Manual notation.

These circulating currents result in the production of a field in the magnetic structure of the receiver. This field, being angularly aligned with the shaft position of the receiver and the now displaced rotor shaft, results in a torque which restores the receiver rotor shaft to alignment with the transmitted angle. This is the simplest form of repeating position information. Repeaters of this sort are used to report many different types of information from control surfaces and from air-borne electronic equipment to the pilot and, in more sophisticated forms, to automatic flight equipment.
FIG. 3. A transmitter-receiver system.

A-c excitation of the synchro rotors has been standardized at 26.5 volts, 400 cps for standard synchros. The phasing of this voltage is important and the 26-volt excitation leads have been arbitrarily assigned the names "hot" (H) and "cold" (C) for the 26-volt "hot" lead and the ground lead, respectively, so that the rotor excitation may be standardized.

10. Synchro Control Transformer. A different version of the synchro system is the case in which a synchro transmitter operates with a receiver-repeater but where the receiver rotor does not have a-c power supplied (Fig. 4). Instead, the rotor is designed to supply control voltages which reach a null when the control transformer rotor is in effective alignment with the transmitter rotor. If the transmitter or the receiver rotor 's moved so as to disturb the alignment, the voltage appearing across the rotor of the ontrol transformer varies as the sine of the angle of displacement. This voltage is in ect an error signal and the voltage taken from a control transformer may be used to

actuate a servo amplifier which, in turn, drives a motor geared so as to restore the control transformer shaft to alignment. It may also be used, after further processing of the signal, to operate indicator needles which indicate left-right or other intelligence.

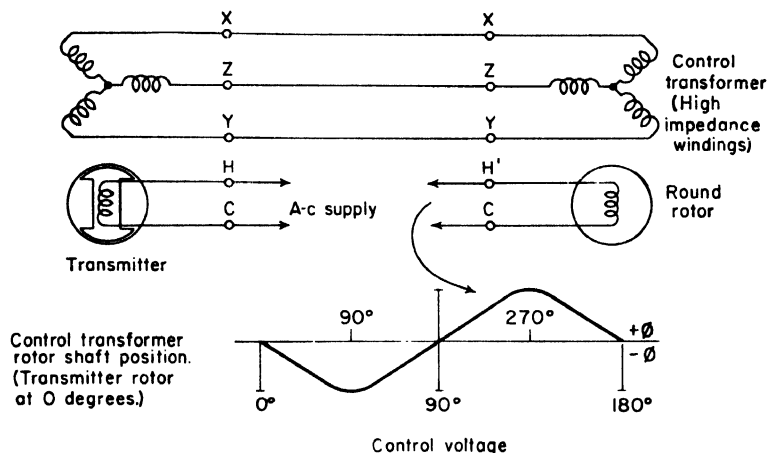
A servomechanism loop using an error signal from the control transformer can perform the same functions as the human pilot who responds manually to correct for changes in flight attitude. Suppose that the synchro transmitter is tied to a control surface of the aircraft and we wish to repeat the position of this control surface in an


FIG. 4. Synchro control transformer.
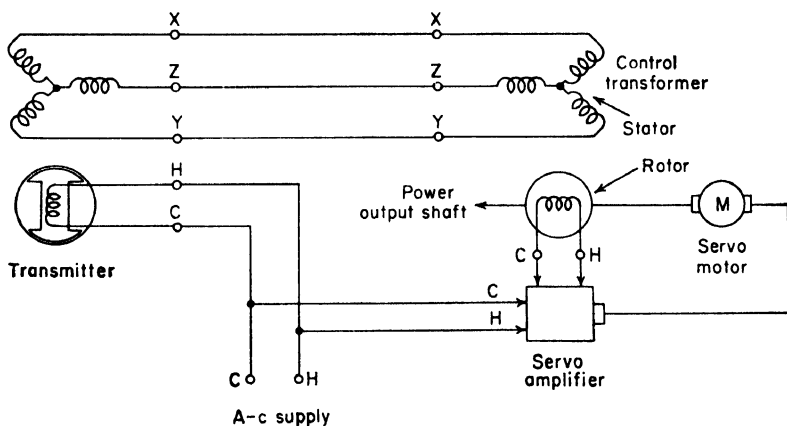

FIG. 5. Basic diagram of servosystem.

electronic device such as an automatic pilot. Assume further that turning the receiver rotor in the automatic pilot requires more power than can readily be transmitted from the synchro transmitter. In this case displacement of the transmitter shaft by the motion of a control surface results in a reorientation of the magnetic field of the synchro control transformer; this, in turn, results in a voltage being induced in its rotor. This induced rotor-error voltage is now amplified to a level sufficient to drive servomotor *M* (Fig. 5) in a direction to restore the control transformer shaft to its original alignment position. In this closed-loop system, it is apparent that the size of the

amplifier and motor may be increased virtually without limit and it is thus possible to supply large amounts of shaft power under remote control through a synchro-controlled servosystem.

11. Synchro Differential Transformer. If we wish to influence the operation of the repeater not only by the position of the transmitter synchro rotor but also by an external influence, we can introduce a *differential transformer* between the synchro transmitter and the synchro repeater (Fig. 6). In this case, rotation of the differential transformer rotor inside the stator will result in a redistribution of the X, Y, Z voltages reaching the repeater. The resultant torque on the repeater shaft and the realignment of the repeater pointer to a new angle will equal the sum or the difference (depending on the connection of the differential) of the originally transmitted angle of the transmitter rotor and the mechanical shaft angle induced through the rotation of the differential rotor. This arrangement provides a means of influencing a repeated signal from more than one information source.
FIG. 6. Basic diagram of synchro differential system.

12. Transition to Automatic Flight. Utilizing the tools described above, we are now ready to discuss the process of automatic flight in relation to manual flight because we have described the electrical and electromechanical means to develop attitude and direction sense information required in the aircraft aloft and the methods of transmitting this information in electrical form to the automatic-flight device. Let us examine the simplest form of automatic-flight control in which we merely wish to maintain the aircraft on a straight and level course. For our reference of level flight, we utilize a vertical gyro which can render position information both in roll and in pitch from separate gimbals. By utilizing a synchro transmitter to detect the angular difference between the position of the gyro rotor wheel (always level) and the gimbal in the pitch axis (which is, in effect, attached to the aircraft) we develop a signal out of the synchro transmitter proportional to the pitch deviation of the aircraft from level flight. This deviation signal is then processed in the elevator servoamplifier and the signal is tailored so that at the output of the elevator servoamplifier is a signal which can be applied, after conversion to a mechanical force, to the aircraft elevators to correct for the pitch-attitude deviation. The signal from the servoamplifier is applied to the elevator servomotor which actuates and drives the elevator surface. A synchro transmitter located on the elevator itself reports back the position of the elevator with respect to the aircraft. If the aircraft is in level flight and the elevators are in their normal level position, the elevator synchro is at equilibrium and no error signal is sent

to the pitch-stabilization system from either the gyro or the elevators. If the elevator is not in its normal level position, an error signal is passed back to the stabilization system indicating that a pitch-attitude correction is taking place in response to an error signal generated in the gyro, thus continually reporting back response information. In this fashion, we can establish a closed-loop servomechanism between the vertical gyro pitch-axis synchro and the elevator synchro. The closed-loop system tends to maintain equilibrium with the aircraft in level flight. The vertical gyro synchro signal announcing an error in the aircraft level causes an excursion in the elevator position. This position change is reported back to the stabilization system by the elevator position synchro. At equilibrium, both synchro signals are at null and the system is at rest.

For *roll stabilization* in the aircraft, the system is very similar. In this case, the basic sensing is done by connection of the synchro to the roll axis of the vertical gyro. Now the servomotor actuates the ailerons with repeat-back synchros transmitting information on the aileron excursion back to the roll-stabilization system. Here again the roll repeat-back signal is sent back to the servoamplifier where it opposes and reduces the error signal from the roll synchro.

The *yaw reference* in modern autopilots is usually established by the signal from the magnetically slaved gyroscopic compass. This gyro spinning about a horizontal axis is similar in nature to the vertical gyro and operates in a similar fashion. A magnetically slaved gyro prevents the drift of the reference direction which would occur in a normal gyro assembly because of friction and unbalance.

When the airplane turns in azimuth, an error signal is developed in the heading synchro of the magnetically slaved gyro compass. Deviations of the airplane about the yaw axis result in rotation of the heading stator with respect to the rotor and a signal to the rudder servoamplifier, causing servoactuation of the rudder surface and the servo loop action described above.

Up to now, the automatic pilot only retains the aircraft in straight and level flight on a constant heading. By a further useful function of most *autopilots*, the pilot can select certain rates of roll resulting in controlled turns and can select rates of climb by introducing artificial error signals. Finally, the slaved gyro compass provides heading data useful as basic information to the pilot in determining his true heading as well as to the autopilot in maintaining a constant heading. Knowing his course to destination and being able to read his true heading from a heading synchro repeater located in the cockpit, the pilot can adjust the heading to make good his desired flight path.

Modern autopilots are also provided with facilities that permit navigation information to be automatically inserted to make the autopilot do additional duty. By using ground-based electronic aids, the autopilot can become the medium for automatic control of approach to an airport. Provision of altitude information from an aneroid altimeter or from a radio altimeter system will permit the autopilot to maintain the aircraft at a constant altitude.

In applying external navigation-system signals to an autopilot, the human-pilot processes remain similar to those of manual flight except that, instead of manipulating rudder pedals and the stick, the pilot may manipulate the "selector" controls of a radio receiver. The radio receiver acts as the "sensor" in detecting deviations from the ground reference chosen and produces error signals as a result of such deviations. These signals are set into the autopilot "coupler" which converts the electrical signals into mechanical energy for the "actuation" of the aircraft control surfaces which through their synchros report their position back to the autopilot. Thus the selector-control-sensor-coupler-actuator discussed earlier applies as well to the control sequence of flight by an automatic pilot as to flight by the human pilot even though the "sensors," "couplers," and "actuators" are no longer the eyes and hands of the pilot. Primarily the "selector," or decision-making element, remains in the pilot's hands.

It may be seen that the automatic pilot, while a great boon in manned aircraft, becomes an absolute requirement in the operation of guided missiles. Here, the "selector" function must also be taken over by a machine—a program computer—

which is given its directions prior to the flight and which cannot normally be corrected for changes of situation or plans after the missile has once begun its operational flight.

The internal signals from navigation aids or computers which may be used to couple additional intelligence to the automatic-flight system are discussed in subsequent parts of this chapter, as well as the technical details of specific electronic pilotage systems. In each case the basic principles of synchro systems and servomechanisms are used to couple the various signals into a useful operating mechanism.

ELECTRONIC AIDS TO AIRCRAFT MISSIONS

Electronics in aviation has gone far beyond its use as a communications medium even when communications is considered in its broadest terms to include communication, navigation, and air-traffic control. Hundreds of devices and systems have been developed to help an aircraft and its crew to perform more adequately intended missions. In the military aircraft such electronic systems as fire-control equipment, bombing systems, search radar, and electronic countermeasures are examples. In the civil-transport field engine analyzers, electronic fuel gages, fire detectors, and weather radar are used. Many of these tools are not unique to aircraft use and are merely extensions of similar use on the ground and on shipboard. Hundreds of special devices of limited applications are used in specialized types of aircraft operations.

Although it is not the intent of this chapter to delve deeply into specialized aspects of aviation electronics, a review of three or four typical devices follows.

13. The Engine Analyzer. This is a device intended to provide continuous visual analysis of an aircraft power plant. Its purpose is to detect and locate malfunctions and imminent failures that may occur during engine operation. Basically, it is an adaptation of an oscilloscope to observe the transient behavior of an engine during the combustion cycle. The voltages displayed are taken from the primary circuit of the aircraft ignition system or from a vibration pickup on the engine cylinder or any other voltage detectors depending on the engine functions to be observed. The sweep of the engine-analyzer oscilloscope is adjusted to show the vibration or firing patterns of either one cylinder or the entire group of cylinders to show a complete engine cycle. Synchronization is obtained from a three-phase generator on the auxiliary tachometer drive whose output voltage alternates in step with the engine and is used to trigger the sweep of the oscilloscope just prior to the firing of any desired cylinder.

14. Fire-control System. In a modern combat aircraft traveling at extremely high speeds, the total time during which one aircraft can be within firing range of another is extremely small. At high speeds, the time required after the completion of a pass at an enemy to get into firing position again is so long, comparatively, that a fighter aircraft may have very few chances at combat with another aircraft also traveling at high speed. Further, the time required to aim and fire a gun manually is much too long for the gunner and gun to be an efficient weapons system. For example, if a fighter aircraft traveling at 1,000 knots engages a bomber traveling at 800 knots in the opposite direction, a relative speed of 1,800 knots is attained. This means that the two aircraft are approaching each other with a relative speed of more than 3,000 fps. By the time the fighter pilot has found the enemy, taken aim, and made the decision to fire, many knots will have been traveled by both combatants and not only will the aim be incorrect but the chances are that the aircraft will be out of each other's range. To solve this problem, search radar is used to scan the sky for more miles than any human eye can see. Once an enemy is detected, the search radar locks onto him and fire-control computers go into action to compute a trajectory based on the position of the enemy's velocity and direction as well as the velocity and direction of the originating aircraft. Upon the completion of this computation the weapon may be fired automatically and without interference from the pilot. Air-borne fire-control systems are complex and critical devices utilizing not only the principles of radar but also highly refined computing devices. It is to be noted that, in the fire-control system, just as in many other electronic systems aboard the aircraft, information from the air-

craft-attitude-indicating devices (the vertical and directional gyros) is important in rendering information on the present situation of the aircraft.

15. Air-borne Weather-penetration Radar. A recent innovation on air transport and executive aircraft is the use of air-borne radar to detect and display precipitation-bearing clouds. It is the property of radar operating both in the X-band (3-cm) and C-band (6-cm) regions to display echoes not only from metallic objects or the earth but also from precipitation-bearing clouds. The weather-penetration radar takes advantage of the fact that clouds in which the precipitation gradient is high present distinctive echoes on the air-borne radar *plan-position indicator* (PPI). Clouds which have a high precipitation gradient are particularly turbulent whereas many clouds in which the precipitation gradient is low even though the total precipitation content may be high are not so characteristically turbulent. On the PPI, the various types of clouds containing precipitation present characteristic shapes so that the pilot can detect and avoid areas of heavy turbulence. By observing, on the PPI, the corridors which may exist between adjacent storm clouds, the pilot may find a calm path through what may appear to be impenetrable weather.

Peak pulse power of 50 to 75 kw is used in the weather radar, and while present-day equipment utilizes conventional cathode-ray tubes, development of bright-view storage tube indicators is nearly complete. These indicators not only have the advantage of providing greater brightness for daylight use, but also permit the displayed picture to remain on the PPI until shortly before a new sweep comes along to paint a new picture. The weather radar utilizes information from the vertical gyro in the aircraft to stabilize the antenna.

16. Electronic Countermeasures. One of the most complex and troublesome problems in military aviation is the development of electronic countermeasures and techniques to resist an enemy's electronic countermeasures. Unfortunately, most electronic systems involving electromagnetic radiation are subject to interference by other electromagnetic radiation. For example, a communication system utilizing voice as the intelligence-transmitting medium from one aircraft to another may be interfered with by a third aircraft generating noise on the same frequency on which the air-to-air conversation is attempted. Pulse systems are often susceptible to interference by continuous-wave electromagnetic radiation.

In the military sense, the development of electronic countermeasures to interfere with ("jam") an enemy's transmission and the simultaneous development of measures to prevent an enemy from interfering with our own systems involving electromagnetic radiation go hand in hand. Noise generators, frequency-seeking devices which permit rapid acquisition of the frequency the enemy might be using, and the generation of pulse groups to interfere with pulse systems are only three examples. The development of jamproof electronic radiating systems in our own aircraft is also of great importance. Electronic countermeasures as well as fire-control systems are complex and highly specialized devices. The detailed analysis of systems of this type will not be attempted here.

The above examples of only four electronic systems used in the accomplishment of aircraft function illustrate the extremely diverse nature of aircraft electronic systems.

COOPERATIVE NATURE OF COMMUNICATIONS, NAVIGATION, AND TRAFFIC CONTROL

Of the five major areas in which electronics plays a dominant role in aviation, those of communications, navigation, and air-traffic control are difficult from the systems standpoint. Whereas electronic sensing and automatic-flight equipment and other specialized electronic aids may be complex, these aids are generally independent of ground facilities and relatively independent of other aircraft. An automatic pilot is almost as useful if it is installed in only one aircraft as if every other aircraft in the vicinity is also provided with one. In the areas of communications, navigation, and air-traffic control, an aircraft is not independent of other aircraft and all are dependent on the ground facilities. Because of the many diverse classes of aircraft and ground

facilities and the need for highly coordinated activity between the ground aids and the aircraft users, the problems of providing satisfactory communications, navigation facilities, and a dependable air-traffic-control system are complex. The three categories of aids are closely allied in their application and are interdependent since successful control of air traffic from the ground requires adequate high-speed communications between the controlling agency and the aircraft to be controlled as well as precise navigation aids to assure the aircraft the ability to follow air-traffic-control instructions. This interdependence applies not only to the terminal area where large numbers of airplanes may concentrate in a relatively small geographic area prior to approach to an airport but also in the en route situation where navigation aids and electronic fixes provide the elements of safe separation and control of the traffic flow.

Given a sufficient number of ground navigation aids, an aircraft could fly from point *A* to point *B* without any communications and certainly without any air-traffic-control surveillance. Unfortunately, the aircraft could do this safely only if it were the only aircraft in the vicinity. As more and more aircraft fly in a given area, not only must navigation aids be used but communications must be provided to assure coordination of the flight paths of the different aircraft. Finally, a traffic-control agency must be provided to render the coordination service.

A whole family of electronic aids has been developed for these three functions. Some of these aids are carried aboard the aircraft while others are primarily for utilization by the ground-control agency. The provision of a satisfactory system of communications, navigation, and air-traffic control is complicated by the wide variety of aircraft types and missions to be found in any particular location. Relatively slow-speed aircraft with a minimum of electronic equipment, high-speed military aircraft in which space for this kind of electronic equipment is severely limited, and the air carriers must all share the same airspace and must, if chaos is to be prevented, utilize the same general control agency and essentially the same type of communications and navigation techniques.

The ground agency responsible for controlling the flow of such diverse traffic is faced with another problem. Electronic aids to navigation and air-traffic-control service must be provided to the major traffic hubs, such as New York, Washington, Chicago, and Los Angeles, using every possible technique available to speed communications and traffic control, and must, at the same time, provide service over relatively lightly traveled areas of the country, without compromising the basic compatibility between the types of aids used. Under the different circumstances of military missions, the problem is further complicated. While the civil communication, navigation, and air-traffic-control facilities can be used in peacetime and within the established ground-facility arrangements all over the world, in wartime the provision of this service becomes complicated because the traffic hubs are mobile and navigation aids as well as communication and traffic-control facilities are subject to rapid and violent changes of location and emphasis.

Subsequent sections of this chapter will deal with the areas of communications, navigation, and traffic control separately, but the reader will do well to keep in mind the interdependence of the three types of facilities.

THE DEVELOPMENT OF STANDARDS FOR AVIATION ELECTRONICS FACILITIES

The several groups of users of the airspace each have individual requirements for electronic aids to communications, navigation, and air-traffic control. If each of the individual user groups were to be supplied with specialized tools to do its own job, our system of airways would be chaos. The airways must be used in common by air-line flights, nonscheduled operators, personal fliers, business fliers, and military forces.

In 1939, there were 27,074 miles of airways implemented with facilities for radio navigation and communications. Control towers were in operation at 52 locations to control the aircraft on and into the vicinity of airports, and 11 air-route traffic-control centers were in operation to control aircraft conducting flights on the airways. The

Second World War was a great stimulant to progress. New equipment was developed and rushed into action. The need was not only for tactical equipment for the fighting zones, but also for improvement of the airways in the United States since every type of aircraft had to move on these airways under poor weather conditions and with all possible speed.

17. The "Common System." The expanding economy of aviation made it quite obvious after the Second World War that the different user groups could not be individually served by different systems of aids, and it was agreed that the various interested private groups and responsible government agencies had to reach agreement on a "common system" of communications, navigation, and traffic control which would adequately serve both civil and military needs. The President-appointed Air Coordinating Committee, organized to investigate aviation problems and developments affecting more than one government agency, agreed that a single group should attempt to resolve the airway problems. The job was undertaken by the Radio Technical Commission for Aeronautics, a cooperative association of United States government and industry aeronautical telecommunications agencies, both military and civil. RTCA, through its Special Committee 31, laid down basic specifications for a common system and proposed a program and equipment to meet them.

The basic principles on which the common system was to be based were as follows:

1. *Safety.* The operation of all aircraft requires that adequate separation of aircraft be maintained at all times and under all conditions.
2. *Expeditiousness.* The expeditious movement of aircraft requires airspace utilization under all conditions equal to that under VFR[1] conditions.
3. *Reliability.* The system shall, as far as possible, be independent of weather conditions and equipment breakdown.
4. *All Aircraft Use.* The system shall be usable by all types of aircraft in a manner compatible with their performance characteristics and operational applications.
5. *All Weather.* The system shall function effectively during all weather conditions.
6. *All Airspace.* The system shall be capable of expansion to include all usable airspace.
7. *Minimum Control.* The system shall provide control that imposes a minimum of restriction on the movement of air traffic.
8. *Integration.* The elements of this system shall be integrated.
9. *Human Factors.* The system shall impose a minimum burden on such human factors as competency, training, and alertness of air and ground personnel.
10. *Evolution.* The system shall permit orderly transition from the utilization of established air-traffic-control aids to those ultimately required.
11. *Flexibility.* The system shall incorporate characteristics which make practicable the handling of a wide variety of operational situations.
12. *Security.* The system shall be designed for due consideration for system security in the interest of national defense.
13. *Limitation of Traffic Flow.* The system in itself shall not limit traffic flow below the acceptance rate of the airports.
14. *Language Difficulties.* The system shall operate independently of the language capabilities of ground and airborne personnel.
15. *Identification.* The system shall provide a means of identifying aircraft as required for purposes of traffic control and in the interest of national security.
16. *Division of Responsibility.* The Traffic Control Agency shall be responsible for air-traffic-control planning, the collection of pertinent information, and the dissemination of traffic clearances and information.

   The pilot shall be responsible for compliance with the control agency's clearances, subject to a primary responsibility for the safe conduct of the flight.

   The appropriate regulatory authority shall promulgate rules and regulations required for the proper functioning of the air-traffic-control-system.
17. *Division of Equipment.* The system shall place the primary burden of weight, volume, and physical complexity on the ground. The aircraft equipment shall result in the minimum detriment to aircraft performance.
18. *Frequency.* The frequency allocation for the system shall be consistent with the National and International Tables of Frequency Allocations.
19. *Cost.* The cost of the system shall be compatible with the results obtained.

[1] "Visual flight rules."

Special Committee 31 was extremely successful in winning acceptance of its findings from all the previously divergent groups, including military aviation, the air lines, the nonscheduled operators, the executive operators, and the private fliers.

Special Committee 31 of RTCA did its work in 1947 and 1948, and while the principles laid out are as valid today as they were then, implementation of the elements of the common system has been a slow process. While there has been general agreement on the job to be done and the principles involved, controversies concerning the implementation of specific tools within the common-system framework have occurred between the various users with divergent interests. In spite of delays, however, progress has been made.

In resolving the problems of the common system, a number of government and nongovernment agencies have a direct stake. The responsible agency for the nation's Federal Airways System, the comprehensive network of navigational facilities, communications, traffic control, and the flight advisory services is the Civil Aeronautics Administration. The Congress has authorized and directed the Administrator of Civil Aeronautics "to designate such civil airways as may be required in the public interest and authorizes him to develop, establish and improve, operate and maintain air navigation facilities wherever necessary, to provide the facilities and personnel for the regulation and protection of air traffic and in the exercise of his authority to give full consideration to the requirements of National Defense." The operation of the Federal airways is an essential element of both military and civil aviation. The common system, however, cannot be the responsibility of any one agency alone. Since it must serve all military nontactical aviation and international aviation as well, a number of different agencies in addition to CAA have a direct stake and responsibility in the development of the common system. Common-system developments are characterized by the tremendous amount of coordination required for their successful implementation, and literally dozens of government agencies, government-industry groups, and industry groups are directly concerned with its development and implementation.

18. The Responsible Agencies. While a separate volume would be required to describe the many agencies involved in the development of the common system and a small library to describe the coordination processes, a few of the most important national and international government agencies who have responsibility in the systems of communications, navigation, and air-traffic control are described.

The five-member Civil Aeronautics Board (CAB) exercises the functions of rule making (including the prescription of rules, regulations, and standards), adjudication, and investigation concerning civil aeronautics. The Administrator of Civil Aeronautics and the CAB constitute the Civil Aeronautics Authority. However, the Civil Aeronautics Authority, as such, performs no functions.

19. The Civil Aeronautics Administration. "The Administrator of Civil Aeronautics encourages and fosters the development of civil aeronautics and air commerce; encourages the development of civil airways, landing areas, and other navigation aids and facilities; designates civil airways and acquires, establishes, operates, and maintains, air navigation facilities along such civil airways and landing areas; makes provision for the control and protection of air traffic moving in air commerce." The activities in air navigation cover the planning, construction, maintenance, and operation of the Federal Airways Systems. The duties of the CAA include the purchase and installation of radio and communication equipment, operation of the air-traffic-control system, maintenance and operation of government-owned air-navigation facilities on the Federal Airways System, conduct of research for development and improvement of new types of equipment to air-navigation aids, aircraft power plants, flight instruments, etc., and furnishing assistance to the Departments of Army, Navy, and Air Force, including surveys, selection of sites, construction, and installation of radio range and communication facilities at points throughout the domestic and foreign zones of military operations.

20. The Air Coordinating Committee. This committee consists of members from the Department of Commerce, the Civil Aeronautics Board, the Department of State, the Department of the Army, the Department of the Navy, Department of the Air Force, Department of the Treasury, Department of the Postmaster General, the Federal Com-

munications Commission, the Bureau of the Budget, and the Office of Defense Mobilization. The committee (ACC) considers joint problems affecting more than one participating agency. ACC develops and recommends "integrated policies to be carried out and action to be taken by the participating agencies or by any other government agency charged with the responsibility in the aviation field and to the extent permitted by law, coordinates the aviation activities of such agencies except activities relating to the exercise of quasi-judicial functions." ACC provides liaison between government and industry activities in the aviation field and also consults with representatives of the United States to the International Civil Aviation Organization and with Federal interagency boards and committees concerned with aviation activities.

21. The International Civil Aviation Organization (ICAO). ICAO is a "specialized agency of the United Nations. The purposes of ICAO are to develop principles and techniques of international air navigation, to foster the planning and development of international air transport so as to insure the safe and orderly growth of international civil aviation, encourage the design and operation of planes for peaceful purposes, guard against economic injustices in international air transport, promote safety and in other ways promote the development of international civil aviation."

"Through ICAO the member states seek to achieve uniformity in all matters where uniformity will facilitate and improve air navigation. Uniformity is achieved through the adoption of Annexes to the Convention known as 'Standards and Recommended Practices.' These Annexes deal with such matters as air navigation aids, airports, rule of the air, licensing of personnel and meteorological information."

22. The Federal Communications Commission. The FCC was created for the purpose of "regulating inter-state and foreign commerce in communications by wire and radio so as to make available as far as possible to all people of the United States a rapid, efficient nation-wide and world-wide wire and radio communication service with adequate facilities at reasonable charges, for the purpose of the national defense, for the purpose of promoting safety of life and property through the use of wire and radio communications."

In aviation, where communication and navigational facilities employing electromagnetic radiations are widely used and vital, the FCC Aviation Division is concerned with the efficient utilization of radio frequencies and the radio spectrum by all classes of aviation. By virtue of this responsibility the FCC is vitally interested in the development and regulation of systems of communications, navigation, and traffic control.

23. The Airways Modernization Board. In 1957, Congress established the Airways Modernization Board with an assigned responsibility to develop, test, modify, and evaluate systems, procedures, facilities, and devices, as well as to define the performance characteristics thereof. It is empowered to select such systems, procedures, etc., as will best serve such needs and will promote maximum coordination of air-traffic control and the air defense system.

The Board is composed of voting members from the Defense and Commerce Departments and a President-appointed chairman. It is envisioned that the AMB, an interim organization, will become the research and development arm of a Federal Aviation Agency, which would consolidate all the essential management functions necessary to support the common needs of military and civil aviation of the United States, except certain air warfare functions.

24. Radio Technical Commission for Aeronautics. RTCA was organized in 1935 upon invitation of the Assistant Director of Air Commerce of the Department of Commerce. Government and industry agencies concerned with the development, application, and use of radio in aeronautical operations were invited to form an organization for the coordination of effort in the technical development of the uses of radio in aeronautics.

RTCA is a cooperative nonprofit association of the United States government-industry aeronautical telecommunications agencies. It conducts studies of aeronautical telecommunications problems and related matters. Its objective is the resolution of such problems by mutual agreement of its member agencies. Its findings are in the nature of recommendations to all United States organizations concerned. The RTCA is not an official agency of the government. Its recommendations, therefore, may not be regarded as statements of official government policy unless so enunciated by the government agencies having statutory jurisdiction in the matters to which the recommendations relate.

25. The International Telecommunication Union. ITU is a specialized agency of the United Nations, having a membership of 90 countries and 5 associate members. The association originated from the International Telegraph Union established in 1865 and resulted from a merger in 1932 into one convention of provisions pertaining to radio, telegraph, and telephone; the 1932 convention was revised at the Atlantic City Conference

in 1947 and at the Buenos Aires Conference in 1952. "The purpose of the ITU is to establish the most efficient and economical systems of telecommunications possible throughout the world, through regulations governing the international use of telegraph, telephone and radio services and through technical and scientific studies designed to improve the means of communication." In the radio field, the chief activity of the ITU has been an attempt to work out, through cooperative procedures, an orderly and equitable use of frequencies in the limited radio spectrum. Periodic international conferences, under ITU sponsorship, have been held to consider regulatory matters and frequencies involved in international fixed (point-to-point) radio, aeronautical operations, high-frequency broadcasting, maritime-service communications, etc.

26. Joint Chiefs of Staff–Joint Communications Electronics Committee. The Joint Chiefs of Staff prepare strategic plans and provide for the strategic direction of the military forces, prepare logistic plans, and assign to the military services logistic responsibilities in accordance with such plans. With the tremendous importance of electronics to the military services, the Joint Communications Electronics Committee advises and formulates plans and policy as they apply to communications and electronics for both military aviation and other services.

27. USAF Directorate of Communications-Electronics. In the Air Force, the Deputy Chief of Staff, Operations, is responsible among other things for Air Force communications activities. The Directorate of Communications-Electronics is directly concerned with aviation-electronics matters.

28. The Air Research and Development Command. ARDC is responsible for the discovery, evaluation, development, and testing of qualitatively superior means for the accomplishment of the Air Force mission, including that of aviation electronics.

29. Air Defense Command. The Air Defense Command is charged with providing for the air defense of the United States and is vitally concerned in aviation matters particularly as applies to the identification, by electronic and other means, of aircraft operating within the United States and particularly near the point of entry.

30. Office of Defense Mobilization. Within the organization of the Office of Defense Mobilization are two coordinating groups having responsibilities which encompass aviation-electronics activities—namely, the Inter-department Radio Advisory Committee and the Telecommunications Planning Advisory Committee. The membership of these groups includes senior communications officials of departments and agencies of the government. They are charged with the development and coordination of telecommunications plans, programs, and actions under work programs established and adopted by the Telecommunications Planning Committee. An important phase of the duties of this organization is to coordinate the assignment and use of radio frequencies, particularly within the branches of the military service.

These are only a few of the many agencies and groups having a vital interest in aviation electronics. It is enough of a cross section to indicate the complexity of developing coordinated plans and programs suited to all these groups. In addition to specific responsibilities for its own phase operation in aviation, each of them must coordinate its activities within the framework of the common system.

AVIATION COMMUNICATIONS

The most venerable use of electronics in aviation is communication by radio. Communication forms the backbone on which all coordinated movement of air traffic depends. It is the link through which aircraft receive information on weather, air-traffic control, clearances, and all other messages bearing on the operation of particular services. Thus communication services are a major part of the system of Federal airways. Further, extensive aviation-communications systems are maintained by the military services for strategic and tactical purposes and by the air-transport companies for operational control of their aircraft.

It is readily apparent that, for the control of air traffic, radio contact between the aircraft and a number of ground facilities is not enough. Efficient operation of air traffic depends both upon air-ground-air communications and upon a rapid means of exchanging intelligence between air-traffic controllers, between the controllers and personnel in flight, dispatch offices, flight services, service centers, communication stations, search and rescue, and air-defense facilities.

The CAA system of Federal airways operates a number of different communication services, both point-to-point (fixed service between ground locations) and ground-air/air-ground facilities.

31. Point-to-point Communications Services. Communications acceptable for transmission and the preferred system for each type of communication are described below:

Service A

1. Emergency communications (of any agency engaged in aeronautical activities) which pertain to or affect the safety of life or property.
2. Meteorological information.
3. Notices to airmen.
4. Meteorological information ordinarily routed on services C and O if offered during periods of communication failure.
5. Aircraft movement and control messages, when existing systems provided for this purpose have failed.
6. Communications having a direct bearing on the maintenance or operation of air-navigation facilities, including official administrative messages of the CAA. This type of communication is authorized only when use of no other communication service, either governmental or commercial, would suffice.

This service is composed, at present, of 12 teletypewriter circuits, each covering an appropriate portion of the United States and having from 100 to 300 terminals (drops) of which about 50 are send-receive and the remainder receive only (total drops, nationwide, about 1,800). The operational weather broadcast on this system consists of hourly service reports, special reports, radar reports, pilot reports, supplementary reports, and miscellaneous data, including a limited amount of upper-air and forecast information required for pilots and dispatchers for operational purposes. Notice-to-airmen information consists of information and advice regarding the status of radio aids to air navigation, airports, and airway lights.

Service B

1. See item 1, service A.
2. Aircraft movement and control messages.
3. Notices to airmen, provided service A is not operative, or when delays, if held for service A transmission, would be excessive.
4. Meteorological information during the failure of other facilities.
5. Communications having a direct bearing on the operation of air-navigation facilities, including official administrative messages of the CAA. This is the preferred type of system for this type of communications.
6. Certain messages filed by Federal law-enforcement agencies.

Teletype circuits are used also to meet the requirements for exchanging intelligence between controllers and between controllers and personnel in flight-dispatch offices, etc., but only to a limited degree for the transmission of control messages, because of current relatively slow operating speeds. It is also used for transmission of international flight safety messages between OFACS. The service B network provides a circuit to serve each air-traffic-control center's area and to provide certain essential "express" circuits and automatic relay between all circuits. The service B speed of operation is in the process of being increased from 75 to 100 wpm. Extensive use is expected to be made of service B for the exchange of less critical control messages between the air-route traffic-control centers and thus relieve congestion and permit more rapid exchange of the time-critical messages on service F.

Service C

1. See item 1, service A.
2. Meteorological information.
3. Meteorological information ordinarily routed via services A and O if offered during periods of communication failure.

4. See item 5, service A.
5. See item 6, service A.

Service C is composed of six teletype circuits, each covering a selected area of the United States and averaging about 75 drops in the offices of a widely diversified group of users.

In the main the data consist of synoptic information used for forecasting and general public weather service. (This service includes periodic synoptic reports, winds-aloft data, terminal, regional, and state forecasts, and various types of weather analyses.)

Service F

1. See item 1, service A.
2. Communications essential for the efficient control of air traffic.
3. Aircraft-movement information offered during periods of failure of service B. Individual weather reports ordinarily routed via other systems, if offered during periods of communications failure.
4. See item 6, service A.

Service F using interphone is primarily employed for time-critical messages. Some of the requirements for exchange of intelligence between controllers is met by talking directly, by telephone, between operating positions within a center or tower. The interphone service F messages have made it possible to segregate control messages from routine aircraft-movement messages, the interphone being used for control messages and the teletypewriter for the transmission of aircraft-movement messages between centers.

Service O

1. See item 1, service A.
2. Meteorological information.
3. Meteorological information ordinarily routed via services A and C if offered during periods of communications failure.
4. See item 5, service A.
5. See item 6, service A.

Service O is composed of 5 circuits serving 90 locations. The data transmitted over service O consist of operational and synoptic weather data received from or having to do with locations beyond the continental limits of the United States which require delivery to key international terminals and large forecast centers within the United States.

32. Ground-Air-Ground Communications Facilities. CAA also renders several different services air to ground and ground to air:

The Air Traffic Communications Station (ATCS). An ATCS is a specialized aeronautical communication station operated by CAA to provide communication between pilots and air-route traffic-control services and to provide flight-information and flight-assistance services primarily to military, itinerant, and other non-air-carrier users. Other functions of the ATCS's are the operation of a land-line system for the collection and dissemination of weather information and the exchange of aeronautical safety messages and to monitor the performances of nearby navigational aids and to initiate remedial actions in case of their malfunctioning.

The development of the ATCSs began with the establishment of low- to medium-frequency range facilities to provide voice weather broadcasts over the radio-range frequency. This soon expanded to two-way communication using the voice channel of the radio range for the ground-to-air channel. As activity increased, separate air-ground communications, independent of the navigational service, were added. Coordination between such stations was provided by secondary use of the point-to-point teletypewriter system which, in turn, was later supplemented with separate services for each of these functions.

The ATCSs became an indispensable part of the air-traffic-control system, particularly as contact points for military and non-air-line civil aircraft. Some of the activities of ATCSs may be displaced with the increase in direct center-to-aircraft communications.

As an indication of service rendered by interstate airway communication stations, 6,817,657 individual aircraft contacts were made during fiscal year 1955. Of these con-

tacts, nearly 4 million were aircraft operating under instrument flight rules (IFR) and defense visual flight rules (DVFR). The distribution of these aircraft was 71 per cent military, 11 per cent air carrier, and 18 per cent other civil. The small percentage of air-carrier aircraft contacted through ATCSs results from the fact that the air-line needs are met by the nongovernment air-transport-company facilities.

International Air Traffic Communications Station (IATCS). IATCS is a CAA aeronautical telecommunications facility for maintaining aeronautical communication services between the United States and its territories and possessions and foreign locations in the major world-air-route system. These stations provide the means for collection, dissemination, and exchange of international meteorological data, the handling of the necessary categories of aeronautical safety communications between fixed points on international air routes, and the handling of air-ground communications associated with international air operations. Ten major facilities are now in operation by the CAA, and these facilities provide services in accordance with standards established by the ICAO. These facilities fulfill a part of the United States responsibilities under ICAO international agreements as a portion of the world-wide service to aviation coordinated by that organization.

33. Direct Center-to-pilot Air-to-ground Communications. This facility provides for the use of air-ground communication channels by air-traffic controllers in air-route traffic-control centers for direct contact with pilots for the purpose of expediting the control of en route traffic. In the control of traffic, particularly in congested areas where there may be a large number of high-speed and low-speed aircraft intermixed, the use of direct communications between controller and the pilot has proved to be an efficient way of conveying traffic-control instructions in minimum time. Direct communications permit more rapid pilot acknowledgment and compliance with ATC instructions than is possible when traffic-control instructions are relayed between controller and pilot via an intermediary, and permit the handling of a greater number of aircraft. The direct controller-pilot communication system also expedites the control of air traffic in that it permits direct and rapid coordination between the two parties required in the solution of special or complex control problems. This program is an extension of the direct controller-to-pilot communication system originally inaugurated in airport traffic-control towers to expedite the movement of traffic in the terminal area. It is planned ultimately to provide each control position in the air-route traffic-control centers with a discrete radio-communication outlet to the aircraft under its control responsibility.

34. Operational Control Communications. Several major segments of aviation maintain extensive networks of communications for operational control for the safe and expeditious conduct of the airway users' flights and for the essential communications required to conduct their business.

The U.S. Air Force Communication System.[1] One example of such a system is that in use by the U.S. Air Force, the U.S. Strategic Communications System. This system, separate from the CAA system of Federal airways, encircles the globe with radio stations, land lines, switching centers, and ground-air stations. The domestic United States portion of the system consists of "five major semi-automatic teletype switching centers connected by leased wire trunk circuits. Each switching center has its satellite air base tributary stations. In addition, the USAF Strategic Air Command (SAC) has special leased telephone, facsimile, and teletype lines directly interconnecting United States bases. Important leased-wire lines are backed up by high frequency radio facilities."

The overseas communications lines through the Atlantic, Mediterranean, Middle East, the East, and the Pacific are high-frequency four-channel time-division-multiplex systems. Conversion of some of these systems to single-side-band plus multichannel teletype has been undertaken. The circuits through the North Atlantic area to Labrador, Greenland, and Iceland are v-h-f beyond-the-horizon systems which have proved more reliable than high-frequency circuits. All the v-h-f circuits are either four- or eight-channel multiplex but newly developed equipment may make it possible to double this channel capacity.

The Air Force global communication system handles over 3½ million teletype messages monthly, plus some quarter million ground-air contacts with military aircraft.

[1] Donkin, F. W., Col., USAF, "U.S. Air Force Communications Systems Problems," IRE 1956 National Convention.

Civil Air Transport Company Communications. Part 40 of the Civil Air Regulations concerning communications facilities requires that "the air carrier shall show that a two-way air-ground radio communication system is available at such points as will ensure reliable rapid communications over the entire route either direct or via approved point-to-point circuits for the following purposes:

"(*a*) Communications between airplanes and the appropriate dispatch office, in which case such systems shall be independent of systems operated by the Federal Government, and

"(*b*) Communications between airplanes and the appropriate air traffic control unit, in which case the Administrator may permit the use of communications systems operated by the Federal Government."

To meet the requirements for a separate communications system for company operational control, more than 500 nongovernment air-ground-air communications stations and associated point-to-point land-line facilities are used by air-line companies. This system provides continuous contact between the offices of each air-line company and their aircraft in flight and is utilized for the transmission of CAA flight instructions where these are not covered by direct CAA aircraft communications, for the exchange of weather-advisory information, and the normal details of transport operation. The transport companies also operate teletype circuits and point-to-point radio stations interconnecting their administrative offices for the exchange of communications essential to the safe, expeditious, and economical operation of high-speed mail, cargo, and passenger service.

Aeronautical Radio, Inc. The communication activities of the civil air transport companies are coordinated through the facilities of Aeronautical Radio, Inc. (ARINC), a corporation in which the United States scheduled air lines are the principal stockholders. Aeronautical Radio, Inc., is the FCC licensee of the nongovernment aeronautical ground radio stations. The majority of these stations are located on air-line property and are operated under lease-contract arrangements by the using air lines themselves. A number of these stations, mainly at major points of entry into the United States, are operated by ARINC personnel. All of them serve any air line or other aircraft having contractual arrangements with ARINC for the operation, maintenance, and shared liability of the respective facilities.

ARINC is also the coordinating agency for air-line-industry activities in communications matters. In addition to air-ground-air service from more than 500 locations throughout the United States, ARINC furnishes the international air carriers and others, including the United States government, point-to-point communications service to overseas and foreign points through ARINC-operated aeronautical fixed stations.

The operation of the ARINC air-ground-air service renders to the air lines, and to other contract users, a service which is used in most instances in lieu of the CAA ATCSs. It maintains continuous contact between the aircraft and the appropriate dispatch office for messages of in-flight advisory nature and operational control, although a large part of such communications relate to air-traffic control.

35. Other Aeronautical Services. Several aeronautical services not described in the preceding sections are of interest:

Airdrome Control Stations. Communications of an airdrome control station are intended for the safe and expeditious operation of aircraft using specific airport facilities for operating within an airport control area. The services of the airport control stations include those at the control tower at air-route traffic-control centers for communications with ground vehicles and aircraft on the ground at airports.

Aeronautical Utility Mobile Stations. Using some of the frequencies available to airdrome control stations, communications by an aeronautical utility mobile station takes care of the necessities of ground-traffic control at an airport and is used for essential communications with control towers, ground vehicles, and aircraft on the ground.

Aeronautical Public-service Stations. Certain frequencies available to ship telegraph and ship telephone stations are available also to aeronautical public-service aircraft stations for the handling of public correspondence. Although an adequate public telephone service is not available on a regular basis to the scheduled air carriers or other aircraft operators, planning fro such service as an adjunct to the public long-distance telephone service is under way.

Civil Air Patrol Stations. A number of frequencies are available for the routine and emergency needs of the Civil Air Patrol.

Aeronautical Advisory Stations. These stations may be provided by the owners or operators of landing areas not served by airdrome control stations, for the purpose of communicating with aircraft to advise on the necessities of safety and expeditious operation of aircraft. These stations handle communications primarily concerned with the condition of runways, types of fuel available, wind conditions, weather information, or other information necessary for aircraft operation.

Aeronautical Metropolitan Stations. These stations are intended to provide communications on a limited-area basis for the safe, expeditious, and economical operation of aircraft operating between the main air terminal of a metropolitan area and subordinate landing areas. Such stations normally communicate primarily with aircraft but are authorized secondarily to intercommunicate with other aeronautical metropolitan stations within the same metropolitan area. This service is particularly suited to the coordination of helicopter operations in a metropolitan area.

36. Military Air-traffic-control Communications. While the majority of civil air-traffic control and domestic en route v-h-f communications are confined to the band 108 to 127 Mc (108 to 118 Mc is reserved for radio navigation stations, the v-h-f Omnirange and the Instrument Landing System Localizer Service), military communications are carried on predominantly in the band from 200 to 400 Mc. This was planned to provide one continuous frequency spectrum for interchange of communications among various military services. A large number of channels for this purpose, as well as for the normal military air-traffic control, are available in this band. The transition by the military to the u-h-f spectrum is proceeding rapidly. The CAA, which has the responsibility for communications and air-traffic-control services to military as well as civil aircraft flying the Federal airways, provides a companion u-h-f channel for each v-h-f channel so that, in effect, the v-h-f and u-h-f channels assigned to a particular station function as one station. This provides the advantage of eliminating a conflict between different controllers in use of v-h-f and u-h-f channels, and where this pairing is used, all aircraft in a particular control area receive information concerning other traffic in the area regardless of whether the aircraft are equipped with v-h-f or u-h-f equipment.

FREQUENCY ASSIGNMENTS IN THE AERONAUTICAL SERVICE[1]

37. Airdrome Control Stations. A number of frequencies in the band 118.1 to 126.3 Mc are assigned to this service. These assignments, originally made with a channel spacing of 200 kc on odd-tenth megacycle channels, are now also being assigned on 100-kc spacings as more selective air-borne equipment is becoming available.

121.7 and 127.9 Mc are available for communications with ground vehicles.

121.5 Mc is designated as the universal channel for emergency and distress communications.

278 kc is available for assignment in addition to the v-h-f service.

38. Aeronautical En Route Stations. These stations provide all necessary non-public-service h-f and v-h-f service to any aircraft-station licensee who makes cooperative arrangements. In case of emergencies, these stations provide the above service without prior arrangements.

Several families of frequencies in the band 2 to 20 Mc are assigned for domestic routes in the continental United States.

Groups of frequencies, deployed on a regional basis in the continental United States, are assigned to v-h-f chains in the band 126.9 to 132 Mc.

Other families of frequencies in the h-f band are assigned to the international high-frequency service serving the major world-route areas.

The v-h-f frequency 126.9 Mc is available to aeronautical en route stations serving international operations.

[1] For detailed breakdown of actual frequencies assigned, see Rules and Regulations of the Federal Communications Commission, Part 9, Aviation Services, effective Dec. 14, 1956. Because of the extreme mobility of modern aircraft and the need for flexibility in aeronautical radio operations, the assignment and utilization of frequencies must be coordinated on an international basis. This is accomplished through the ICAO and the ITU (see Secs. 21, 25). National regulations, such as the FCC rules, reflect such international agreements in the use of frequencies in the aviation service.

39. Operational Fixed Stations. These stations are authorized for link or control service or other aeronautical fixed operations.

They may be assigned frequencies in the bands 72.02 to 74.58 Mc at each 0.04 Mc, such as 72.02 Mc, 72.06, etc., and in the band from 75.42 to 75.98 Mc at each 0.04 Mc, such as 75.42, 75.46, 75.50 Mc, etc.; 75 Mc is designated for aeronautical marker beacons.

Operational fixed stations may also be assigned frequencies in the following bands:

952 to 960 Mc
1,850 to 1,990 Mc
2,110 to 2,200 Mc
2,500 to 2,700 Mc
6,575 to 6,875 Mc
12,200 to 12,700 Mc

40. Aeronautical Utility Mobile Stations. Very high frequencies of 121.7 and 121.9 Mc are available.

41. Radio-navigation Stations. *Localizer Stations.* 108.1- to 111.9-Mc channels, separated by 200 kc, such as 108.1, 108.3, and 108.5 Mc.

Glide-path Stations. The band 328.6 to 335.4 Mc.

Aeronautical-marker-beacon Stations. 75 Mc.

Omnidirectional Radio-range Stations. 112.1 through 117.9 Mc and the following frequencies in the 108- to 112-Mc band: 108.2 Mc to 112.0 Mc spaced 200 kc.

Radio-beacon Stations. 200 to 400 kc.

NOTE: Air-navigation facilities are usually operated by the CAA, although the frequencies which these facilities employ are available for licensing by the FCC upon a showing of need where the government is not prepared to render such service.

42. Flight-test Stations. V-h-f and h-f frequencies are available for flight-test stations shared with flying-school stations on a noninterference basis. A number of frequencies in the 200- to 400-Mc band are available for flight-test-station telemetering activities.

43. Flying-school Stations. 123.1, 123.3, 123.5 Mc shared with flight-test stations on a noninterference basis.

44. Aeronautical Public-service Stations. Frequencies available to ship telegraphic and ship telephone stations are available to aeronautical public-service aircraft stations for the handling of public correspondence.

45. Civil Air Patrol Stations. Several v-h-f and h-f frequencies are available for land and mobile stations of the Civil Air Patrol.

46. Aeronautical Advisory Stations. 122.8 Mc is available for communications with private aircraft stations and for communications with private aircraft engaged in organized civil-defense activities.

47. Aeronautical Metropolitan Stations. Frequencies available for aeronautical en route stations are available for assignment to aeronautical metropolitan stations.

NOTES: *Frequency-stability Requirements.* The FCC rules require that the carrier frequency of stations in the aeronautical services shall be maintained within the following percentage of the assigned frequency (this does not apply to certain devices such as radio altimeters, radar, etc.):

(*a*) All aircraft stations on frequencies above 500 kc	0.01
(*b*) All ground stations on frequencies above 30,000 kc	0.01
(*c*) All stations on frequencies of 500 kc or below	0.02
(*d*) Aeronautical fixed stations on frequencies from 1,605 to 4,000 kc	
With power of 200 watts and below	0.01
With power above 200 watts	0.005
(*e*) Aeronautical fixed stations on frequencies from 4,000 to 30,000 kc	
With power of 500 watts and below and with power above 500 watts	0.003
(*f*) All other ground stations on frequencies from 1,605 to 4,000 kc	
With power of 200 watts and below	0.01
With power above 200 watts	0.005
(*g*) All other ground stations on frequencies from 4,000 to 30,000 kc	
With power of 500 watts and below	0.01
With power above 500 watts	0.005

In general practice, much tighter tolerances are maintained.

H-f Frequency Assignments. Because of the great variations in high-frequency propagation conditions at various times of the year, under different conditions of sunspot activity, and under many short-term propagation conditions, various families of frequencies in the

h-f band are assigned to the several services to permit flexibility and continuous service under the varying conditions. A typical family of frequencies would consist of three or more frequencies from the 3-, 5-, 8-, 11-, 13-, and 17-Mc orders.

V-h-f Channel Spacing. Although the present channel spacing is 200 kc in the band 126.8 to 132.0 Mc, additional intermediate frequencies at 100- or 50-kc spacing may be authorized for use if it is shown that harmful interference will not be caused to aeronautical en route stations operating on v-h-f frequencies. Frequencies in the air-traffic-control service in the 118.1- to 126.3-Mc band, while normally assigned with 200-kc spacing, may also be deployed on a 100-kc spacing basis according to criteria established by a special committee of RTCA. These more closely spaced channels as well as the 50-kc spaced channels falling between them will be used with due regard to interference protection as more selective air-borne receiving equipment becomes generally available.

48. Recent Developments and Trends in Aeronautical Communications. Both the h-f spectrum and the v-h-f spectrum are extensively used. While the h-f service is extremely important, particularly for long-haul operations where other methods of communications are not feasible or satisfactory, the v-h-f service offers better intelligibility, freedom from static, less exposure to interference, and more positive geographical coverage even though confined to line of sight. With the domestic United States, the program for the CAA air-traffic-control-system expansion anticipates the continued and expanded use of v.h.f. for civil operations and the u-h-f spectrum for military operations. With the limited amount of frequency spectrum available for civil v-h-f communications, the problem of obtaining additional frequencies to serve the ever-expanding aviation industry becomes a serious one. A long-range plan, coordinated several years ago by RTCA, which had to await technical and economic capability, is now being implemented. This provides more u-h-f frequencies by channel splitting, thus utilizing the intermediate frequencies spaced 100 kc instead of the 200-kc spacing previously used. A further step, to 50-kc spacing, is contemplated as economics permits. Both CAA and the air carriers are taking these steps to afford useful increase in the total number of available channels and the more efficient utilization of that portion of the spectrum available to aviation.

49. V-h-f Networks. Voice communications by v.h.f. is naturally limited by the line-of-sight character of v-h-f radiation. Where extensive en route coverage is required of v-h-f communication service, careful siting of ground facilities is employed to assure the desired route area coverage. Ground stations may be used singly or in tandem. One method involves the simultaneous transmission and reception from the various ground stations, so that aircraft may be assured at any time of receiving signals from one or more ground transmitters, each of which carries the same message content. Such interconnected chains of stations are in use in Europe for air-traffic-control networks and are being implemented in the United States for certain segments of the air-transport industry.

The same nominal v-h-f frequency is used for several interconnected ground-network transmitters which transmit the same information simultaneously. The discrete frequencies used by the several transmitters are offset a few kilocycles to either side of the center frequency. All transmissions remain within the pass band of the air-borne receivers. Since aircraft at higher altitudes may receive signals from one or more ground transmitters at a time, and frequently do, care is taken to assure audio modulation of the several transmitters in phase, precision control of frequency in the ground transmitters, and the careful design of aircraft receivers to provide sufficient attenuation of objectionable heterodynes falling within the audible range.

50. Selective Signaling. Aeronautical stations are operated on the network principle, using the radio circuit as a party line. Several stations geographically spaced along the flight route share a common frequency. Circuit discipline is accomplished by "listening before talking." Coordination of flight coverage by ground stations is accomplished by intercepting and relaying essential reports. Calls are directed to the desired flight or ground facility by so designating as a prefix to the message. The aircraft crews as well as the ground operator are forced to listen continuously to be assured they respond to all calls directed to them. Considerable valuable information

is intercepted through this monitoring process, but this is becoming less important as the pilot is becoming more self-sufficient through information continuously available to him by electronic aids and the air-traffic-control system. However, the communication function is still essential and in the course of a long flight, particularly when h-f circuits are used, pilot or operator fatigue can cause missed messages, particularly when the signals are weak and nearly lost in noise. If the same principle used in the telephone were applied, so that a particular aircraft need not listen to all communications on a particular channel but could wait until his particular aircraft is discretely contacted, a great deal of the unproductive listening could be avoided. A number of different calling methods have been developed to provide a discrete address or a call-up signal to particular aircraft.

51. SELCAL. One system going into wide implementation among the air carriers is a system known as SELCAL. Primarily used in h-f circuits at this time, although later application to v.h.f. may follow, this system utilizes discrete tones as a calling signal. Two pulses made up of two audio tones each are transmitted sequentially. The air-borne receiving equipment is fitted with reeds which respond only to the specific tone-frequency group to which the aircraft is set. By using the combination of two pulses, each made up of two separate tones, nearly 3,000 high-quality tone groups can be attained from a basic system using 12 tones. By assigning a tone group to a specific aircraft, that aircraft need no longer listen continually on a specific channel but can wait until the SELCAL signal lights a signal lamp or sounds an audible tone in the aircraft cockpit. The SELCAL system has already proved itself in long-haul operation on h-f and promises useful application on v-h-f services as well.

Many different methods of selective signaling are possible and can be designed to provide almost any number of different "addresses."

52. Scatter Propagation. While v-h-f and u-h-f transmission is generally considered as limited to line of sight, a method of over-the-horizon, or *forward-scatter*, transmission has recently been developed to provide reliable communications at distances greater than can be expected of normal v-h-f or u-h-f signals. Inhomogeneities in the troposphere, caused by irregularities in the spatial distribution of electron density, cause the so-called scatter which permits transhorizon communication. In v-h-f scatter systems the signal received over a scatter circuit is of low level although transmission is accomplished at relatively high power. Large directive antennas are used along with very sensitive receivers. Since "scatter" propagation via the ionosphere or troposphere paths is characteristically persistent, improved reliability should be attainable, as opposed to high-frequency communication systems in which frequent and rapid frequency changes are necessary to assure circuit continuity.

Transhorizon circuits are thought to be practical for long-distance transmission of both voice and teletype. They show good promise for voice communication although meteoric interference and flutter caused by signal reflection or aurora may limit the transmission quality. From a propagation standpoint, it is believed feasible that teletype transmission of very high reliability will be obtained from transhorizon systems, although very high power levels are required.

53. High-speed Automatic Communications. As air traffic increases, the need for communication rises as well. In preceding sections, the program for direct center-to-pilot communications has been reviewed and several means for obtaining more radio channels have been described. More and more communication channels and more and more talk over these channels provide for more rapid access from aircraft to the ground controller and from the ground controller to the specific aircraft under his control. However, as more aircraft operate within a terminal area, for example, the need for frequent information on the aircraft position becomes greater. While the situation is helped by providing more communication channels to serve individual control functions, the pilot of a modern aircraft must very frequently change frequencies as he passes through various control areas. It will be seen from later discussion that the growing communication load can introduce delays in the control of air traffic. It is

clear from traffic analyses at particular airports that the message capacity of radio-telephone of somewhere around 200 wpm is too slow to cope adequately with the growing communications load.

The communications load increases at a much higher rate than the increase in air traffic itself, so that limited communications capability will specifically limit the ability of traffic controllers to control flight movements.

In the terminal area the information transmitted during approach and landing involves only a restricted vocabulary. Nearly one-half the talking is concerned merely with the routine mechanics of keeping the process in operation, such things as identifications, acknowledgments, and tests. The remaining time is spent in transmitting information essential to control, such as clearances, position, time, and weather.

One of the major elements of the communications between controller and pilot is the transmission of position reports from air to ground and the resulting control instruction developed by the controller on the basis of these position reports and those from other aircraft in the vicinity. The continuing rapid expansion of air traffic has prompted study and development of automatic high-speed communications, both ground to air and air to ground. While such systems are essential in the military service for the rapid scrambling of military combat aircraft, high-speed communication and rapid access to a large number of aircraft using our domestic airways are becoming increasingly important.

54. Ground-Air Communications. For ground-air communication, the controller must be able rapidly to address a specific aircraft, transmit his message, and receive an answer or an acknowledgment. Much of the ground-air communications is formalized, the variation between messages often being only one number, such as altitude. In the instruction to orbit over a fix, the location designator and altitude over the "fix" may be the only variables. It appears that a high percentage of any ground-air message is routine, although only a few complete messages are routine in their entirety.

A number of different ground-air high-speed communication systems have been considered. A typical one is a digital ground-air link in which advantage is taken of the fact that the total information content of typical ground-air messages is very low. Using a binary system similar to that used in conventional teletype circuits, relatively few bits of information are needed to transmit ground-air control messages. Thus, relatively small band width is needed for this type of system and the message rate can be quite high.

Another of many possible approaches to high-speed communication is a slow-speed television system. In this arrangement, the "camera" is focused on a display of information intended for a particular aircraft and this picture is transmitted over a relatively narrow band width to a receiver perhaps already in the aircraft and is displayed to the pilot. This system has the inherent advantage of the redundancy implicit in the transmission of a picture and permits a visual check by the pilot of the discrete address which can be a part of the transmitted picture.

55. Air-Ground Communications. An air-ground message suitable for high-speed automatic transmission might consist of a position report derived from the aircraft navigation instruments. For example, if both azimuth and distance information is available in the cockpit from ground aids or other instruments, and altitude information is also available to the pilot, a telemetering system might be utilized to send this information automatically air-to-ground upon receipt of an automatic ground-air message. Any of several practical telemetering systems might be utilized for the air-ground portion of an automatic communication system which would, as described here, fall in the category of an air-traffic-control signaling system. Obviously, many items of information might be transmitted air-ground and ground-air to simplify and expedite the air-traffic-control job. The primary requirements for this kind of signaling system are extreme reliability, relatively small band width, and if possible the capability of utilizing transmitting and receiving equipment which already exists in the aircraft.

A high-speed air-ground-air communications system (AGACS) provides three basic elements of information handling:

1. *The Discrete Address.* This is the means whereby the ground operator can, by initiating an action or by a routinely programmed method, contact a specific aircraft by in-flight number or other designator. The discrete address should be automatically checked either by a redundancy check back to the ground or by sending the message address in such a fashion that there is no way to mistake it in the cockpit.
2. *The Ground-Air Message.* The message will consist of the salutation, which is a discrete-address display to the pilot, and the actual message content.
3. *The Air-Ground Reply.* The air-ground reply might consist of an automatic transmission of certain aircraft-position information in response to a request made automatically from the ground, as well as certain yes-no replies, such as "acknowledge," "activate," or "reject," to the message sent on the ground-air path.

It is to be noted that, while an automatic high-speed communication system might render very great assistance to the process of air-traffic control by expediting communications, it is unlikely that all ground-air traffic-control communications can be handled by automatic means. Certain nonroutine messages would probably take longer to prepare for automatic transmission than to transmit on the voice channel. Further, special communications and emergency communications would doubtless be retained on a voice channel. One particularly attractive feature of narrow-bandwidth automatic communication systems is that they present the possibility of multiplexing automatic communications on channels now used for voice communications alone.

IMPLEMENTATION OF THE FEDERAL AIRWAYS WITH COMMON-SYSTEM ELEMENTS

As described in Chap. 26 on navigation systems, many different types of aids have been proposed for use in the common system and many others which, although they have certain specific merits, have not been suggested for incorporation in the system of Federal airways. It is to be recalled that the system of Federal airways and the elements of the common system are intended to take care of the communications, navigation, and air-traffic control for both military and civil users but are not intended to take care of special tactical situations. Thus many highly specialized navigation devices of particular use in combat or other military tactical missions are of little concern to the common system except in so far as care must be taken to prevent interference between different systems which might be used for different purposes. The following is a brief description of some of the navigation aids which make up the major elements used in the system of Federal airways and their state of implementation. Although some specific aids have been described in detail above, they are briefly redefined here. Most of the definitions employed are those developed by the Radio Technical Commission for Aeronautics in its Special Committee 47. They are not stated in order of importance.

56. Low- and Medium-frequency Radio Ranges. Low-frequency–medium-frequency four-course radio ranges define four navigational courses which the pilot of an aircraft can locate and fly using a simple radio receiver operating in the 200- to 415-kc band. The courses are defined aurally by an interlocking series of dot-dash (A) and dash-dot (N) signals of equal amplitude. Transmissions also serve the automatic direction finder (ADF) permitting the pilot to fly toward (*i.e.*, "home-on") the station utilizing the visually indicating cockpit instrument. By combining the bearing information with magnetic bearing information, the pilot can determine his navigational line of position.

These stations also broadcast voice and coded identification signals. The voice function is utilized for weather broadcasts, a service which is primarily for aviation but is being utilized widely by nonaviation groups, particularly by farmers. L-f/m-f four-course radio ranges are used to define the airways system of the United States and are in general use throughout the world. Because of service interruptions and deterioration under various static conditions, lack of flexibility in the number of courses provided, and pilot fatigue in the utilization of the service, the system is being operationally superseded by the

VOR. A limited network, however, will probably be operated as a permanent part of the transition-period common system.

The first l-f/m-f radio range was commissioned in 1928. Their number increased rapidly to a maximum of 378 installed stations in 1949. A simple low-cost air-borne receiver is used to receive the course signals and simultaneous voice broadcasts. As of June 30, 1955, there were 346 such ranges in operation.

As outlined above, the system of v-h-f omniranges (VOR) and the ever-growing number of aircraft capable of receiving VOR signals will permit the Federal airways to plan to discontinue use of all continental l-f/m-f ranges by 1959 with the exception of 88 retained for broadcast purposes and limited navigational use.

57. Low- and Medium-frequency Nondirectional Radio Beacon. "This is a general designation for that class of l-f/m-f radio aids to navigation primarily intended for use with mobile direction finders to provide bearing information.

"The *H Facility* is a nondirectional radio beacon operating within the 200 to 400 kc band installed in en route areas to provide navigational guidance, or in the vicinity of an airport as an aid to approach.

"The *Compass Locator* is a nondirectional radio beacon installed at or in the vicinity of the outer marker or the middle marker of the ILS."

The radio beacon signal is received by an air-borne direction finder which shows the pilot the direction (azimuth) from which the ground signal is coming. By using two or more beacons it is possible to establish a fix.

The nondirectional radio beacon was first established by the Bureau of Lighthouses for marine use in 1921. In 1934, a lightweight manual direction finder was developed for aircraft use and shortly thereafter ADF was developed and the air-borne equipments now number into the thousands. There were, as of June 30, 1955, 173 l-f/m-f nondirectional radio beacons in operation.

58. V-h-f Omnirange (VOR). "VOR is the present standard short distance navigation aid facility. It has received international acceptance; a specification is contained in Chapter 3, Annex 10, Standards and Recommended Practices, ICAO, May, 1950.

"The term 'omni-directional radio range' has been used to designate a variety of developments during the past 20 years. It connotes a single-site transmitting facility which radiates a directional signal rotated through 360 deg in the horizontal plane. The character of the signal varies as the signal rotates. The receiving equipment interprets this variable signal in terms of the bearing of the receiver from the signal source."

The development of 100-Mc VOR was initiated in 1937 by CAA. The installations commenced on the Federal airways in 1946. As of June 30, 1955, there were 410 omniranges in operation with an additional 88 facilities in various stages of planning, construction, and test.

59. VORTAC. Because of a specific military requirement for an azimuth system other than the VOR, the VORTAC system has been agreed to by the Air Coordinating Committee as an element of the common system. The VORTAC system consists of a single station which renders three separate services. The first of these is the standard CAA-VOR. In addition, and co-located, is to be a TACAN (Tactical Air Navigation) facility which renders both u-h-f azimuth information and u-h-f distance-measuring service. The plan is for the military users of the system of Federal airways to utilize the TACAN azimuth along with the TACAN distance-measuring service, and for the civil users to use the VOR azimuth service and the TACAN distance, with a possible later transition away from either one of the two azimuth systems.

In the distance-measuring system an air-borne interrogator equipment transmits a signal which is received on the ground. The received signal automatically initiates a ground-station transmission. Upon receipt of this transmission the air-borne equipment measures the elapsed time for the cycle and converts it into a visual indication showing the number of miles from the aircraft to the specific ground facility.

A pulse-multiplex distance-measuring equipment (DME), different from the TACAN distance system primarily in the manner of channeling, had been proposed by CAA and had received international endorsement by ICAO. Because this system is not compatible with the military clear-channel TACAN azimuth and distance system and because of the stated military requirement for the TACAN system, DME stations which had been commissioned for use with VORs were designated to be replaced by the TACAN distance service. Although the CAA pulse-multiplex DME facilities will remain in operation for several years while the transition takes place, it is expected that the pulse-multiplex DME service will be discontinued as the implementation of TACAN systems goes forward to complete the VORTAC system installations.

60. Instrument-landing System (ILS). "Although the designation 'ILS' is an abbreviation of 'Instrument Landing System' the term ILS had been generally accepted to designate the specific system of electronics aid to approach comprising:

"*a.* A *Localizer*, operating within the 108 to 112 Mc band.
"*b.* A *Glide Slope* facility, operating within 328.6 to 335.4 Mc band.
"*c.* *ILS Markers*, operating at 75 Mc.

"As a general term, 'Instrument Landing Systems' is applicable to any type of radio system which employs ground transmitters and fixed directive antennas to define a beam which laterally localizes the runway extension and defines a *slope* plane (as some angle between 2 to 5 deg) leading to the optimum point of touchdown on the runway.

"The Localizer designates the electronic ground element of ILS which provides lateral guidance to a pilot during his approach. Certain instrument landing systems other than ILS also employ electronic elements which give lateral guidance to the pilots during an approach. While such elements may properly be designated localizers this designation should not be employed without suitable modifiers to distinguish such elements from the Common System localizers.

"The Glide Slope facility designates the electronic ground element of ILS which provides vertical guidance to a pilot during an approach."

ILS markers are 75-Mc radio navigational stations (sometimes referred to as *marker beacons*) the signals of which define specific areas along the localizer course line. ILS markers radiate a fan-shaped field pattern in the vertical plane. The major axis of the pattern is normal to the line of flight. The horizontal cross section of the pattern is approximately elliptical. Markers operate a light in the aircraft cockpit to emphasize specific distances from the approach end of the runway.

ILS enables the pilot to make landings at an airport under adverse weather conditions. The precise guidance of the system not only provides safety but expedites the movement of air traffic in the area by reducing the number of missed approaches. Its use provides lower landing minimums and therefore regularity of operations is increased.

The first commercial models were installed in Indianapolis in 1939. As of June 30, 1955, the total of 170 had been programmed with 157 commissioned. The ILS markers, two of which operate as *outer marker* and *middle marker*, are used to define specific locations on the localizer course.

Other uses of the 75-Mc marker system include the *Z marker*, which is a 75-Mc radionavigation station located at an airway l-f/m-f four-course radio range to indicate position above such a range.

61. Other Major Navigation and Traffic-control Aids. A variety of other aids are in use or are coming into use for long-distance navigation. Among others are Consol, loran, and Decca (see Chap. 26). Self-contained aids, using either velocity information derived from Doppler shift measurements or acceleration measurements by inertial means, are coming into use to provide navigation information. With appropriate computers such devices may permit aircraft to fly long distances without reference to ground-based aids, except for periodic correcting fixes. Several other aids, while they basically render navigation information, provide it to the ground station

rather than to the aircraft and thus may become tools of air-traffic control. These aids, including the airport-surveillance radar, precision-approach radar, ground radio direction-finding equipment, airport surface detection equipment, and secondary radar, may be considered primarily aids to traffic control. These are discussed below.

AIR-TRAFFIC CONTROL

Perhaps the most vexing and perplexing problem in aviation is the problem of air-traffic control. The U.S. Air Traffic Control Service is the responsibility of the CAA. The CAA defines air-traffic control as "a service to promote the safe, orderly and expeditious flow of air traffic. In controlled air space the service is furnished both civil and military aircraft. It consists of Airport Traffic Control (control towers), Air Route Traffic Control (ARTC centers), and Approach Control. Approach control is exercised by centers or delegated to towers. From the use of radar has evolved a facility which is named for its original function, a RAPCON (radar approach control), but which is taking on certain air route or area control. Long range radar however is the primary en-route radar facility."

Control of air traffic is not dissimilar in object from the control of ground vehicular traffic but it is tremendously complicated by several significant differences:

1. Air-traffic control requires the surveillance of three dimensions of space rather than two.
2. Where ground traffic requires as its premise the principle of "see and be seen," air traffic control must be exercised in periods when the visibility is good (and one aircraft is capable of seeing other air traffic) but also in foul weather conditions when the visibility is poor and other traffic as well as landing areas are obscured by clouds, fog, rain, or other impediments to vision.
3. While vehicular traffic is essentially all of the same type, that is, all motor vehicles operate within essentially the same range of speed (say from 5 to 90 mph), in air-traffic control the system accommodates traffic whose speeds encompass several orders of magnitude. For example, an aircraft flying at 70 mph may be in close proximity to an aircraft operating at 1,200 to 1,500 mph. The same control system must accommodate all types of air-borne vehicles.
4. Whereas vehicular traffic is restricted to well-defined traffic lanes—the streets and highways—air traffic is capable of operating anywhere in space (up to certain altitude limits) and the traffic-control system must be flexible enough to accommodate air-borne vehicles traveling on defined routes or airways as well as vehicles, such as military aircraft, which may utilize any track in the sky.

62. United States Policy. After long discussion and much soul-searching, it has been agreed that, to be an effective, economical, and satisfactory way of providing for safe and expeditious flow of air traffic, the air-traffic-control system must be a single service which serves all segments of aviation.

The policy of the United States, as pronounced by the President's Air Coordinating Committee in May of 1954, states that it shall be the continuing policy of the United States to

"1. Provide for a single national common civil-military system of air navigation and air traffic control. The national integrated system shall satisfy the air navigation and air traffic control requirements of all civil and air operations except for those special military requirements peculiar to air warfare.

"2. The common system shall be capable of immediate integration with the air defense system of the United States and will constitute an auxiliary to the air defense network.

"3. To provide for an accelerated joint civil military program of research and development to bring and keep the system abreast of the current and foreseeable future operational requirements.

"4. To accelerate the transition to the most advanced concepts of the common system."

Because of the vastly different needs of the various elements of aviation, control of air traffic is a subject which is in continual controversy. Elements of the air-traffic-control system which may admirably serve one segment of aviation are of little or no

use to another. Equipment which involves vast expenditures may be justifiable for one group and totally unattainable to another. It is thus the function of the common-system air-traffic-control development to render a system usable by all segments of aviation.

63. The Function of Air-traffic Control. An air-traffic-control system has been defined by C. C. E. Bellringer, of the International Air Transport Association, as a "closed circuit servo or nervous system wherein the rate of appreciation of a situation change coupled with the time required to take appropriate action must be greater than the rate of change of the actual situation." Stated more simply, although not nearly so well, the following situation might be visualized:

Assume a situation in the vicinity of an airport where a large number of aircraft are deployed.

Some of these aircraft are holding at specific fix points and different altitudes awaiting instructions to land.

Other aircraft, having just taken off, are in the same general area and are climbing from the airport to their assigned altitudes.

Yet other aircraft are overflying the control zone; that is, they have the intention neither to land nor to take off from the airport in question but are merely traversing the airspace to get from one point to another and their path leads them in the vicinity of the airport-traffic-control zone.

These aircraft may be flying in any one of a number of different directions and may be climbing or descending at any particular moment. Additional aircraft from a nearby military base may be practicing scramble and intercept missions and weave in and out of the traffic to simulate the identification of a potential intruder.

Other aircraft such as helicopters may be flying at low altitudes to deliver mail from the airport to the metropolitan area.

It is the function of the air-traffic-control system to be continuously aware of the position of each of the aircraft in the control zone and to plan and provide instructions to the aircraft under control to assure the safe and expeditious flow of traffic. Furthermore, the element of time is vital. The rate of landing and take-off determines the economic utility of air traffic. Economy of time constitutes a major advantage of air travel. Another complication is that the controller's hand is forced by the different classes of aircraft attempting to take off and land at a particular time. Jet aircraft in particular, consuming tremendous amounts of fuel, probably cannot economically tolerate long delays in obtaining permission to take off or land at a given airport. Delays in air-traffic control are cumulative; that is, in a busy area a delay once incurred is difficult to overcome, since traffic tends to stack up, thus complicating the air-traffic-control problem even further.

Thus the job of the air-traffic control is to provide for:

1. An appreciation of the situation as it appears at a particular moment and an appreciation of the manner of change of the situation which is continually taking place
2. An analysis of the situation to determine the appropriate course of action for each aircraft within the traffic-control zone
3. The transmission of instructions to each aircraft to permit it to carry out the desired maneuvers
4. An appreciation of the fact that aircraft under control have followed the instructions, thus rendering a new situation to the controller for further analysis and action

In the tremendously complex task of satisfying the requirements of air-traffic control, electronic aids play a large part, particularly in the situation of the busy control zone. It is clear that where traffic is very light the problem of traffic control is simple. Only when many different aircraft of many different sizes and speeds going in many different directions with many different tasks all assemble in the same locality does the problem of controlling the traffic become a tremendously difficult task.

The areas in which electronic aids can be of help to the controller are as follows:

Communications. Obviously the most important part of an air-traffic-control system is the link between the controller and the aircraft under his surveillance. This

is the life line through which all intelligence passes from aircraft to controller and back to the aircraft. This need not be voice communications but can be automatic transmission and symbolic display of specific information to the aircraft and the controller. Not only is communications important for coordination between the controller and the aircraft but it is equally important to provide the intelligence link between two controllers responsible for adjacent segments of a traffic-control zone.

Location of the Aircraft. While the communications link can provide information on the position and plan of each individual aircraft in a control zone, this information is usually based on the best estimates available from the pilot, who derives the information from his navigational aids or, under visual-flight rules (VFR), from direct observation of things below him. Unfortunately the information available to the pilot is not always accurate enough or complete, so that a method which can give a controller information concerning aircraft whereabouts independent of communication with the aircraft is highly desirable, not only to obtain accuracy on fix for the aircraft but also to correlate the movements of several aircraft in a particular area.

Identification. Another element is the process of identification, whereby a controller needs to correlate an aircraft at a specific location, which he might see on a radar ground display, to a particular aircraft number. Since radar and some of the other position-fixing devices are essentially anonymous, specific identification of a particular aircraft is necessary. The link between an anonymous aircraft and its specific identification as to air frame, aircraft class, and flight plan must be accomplished either by the aircraft performing the identifying maneuvers in response to request and identifiable by the ground operator or by electronic-identification means.

Planning. After information as to aircraft identity and position has been gathered the controller must correlate and formulate plans for the number of different aircraft within a given area. Again, where only a few aircraft are involved a controller might be able to keep the information on aircraft position and their progress in his head and provide air-control service in accordance with his intuitive reasoning. As the number, type, and missions of the aircraft within a particular control zone increase means must be found to perform some of the computations automatically so as to free the controller to make decisions based on the changing situation and give instructions accordingly, rather than require him to spend a great percentage of his time doing the mechanical and routine job of following aircraft positions and movements.

Automatic Communication. Means must be found whereby the communications air to ground and ground to air can be simplified and automatized where air traffic is so heavy as to overburden available communications channels or communication time in continual position reports and movement instructions.

Coordination. Since more than one controller is involved in the movement of air traffic in a large and heavily traveled area, electronic or mechanical means must be found to meet the problem of coordination between controllers so that passing an aircraft from one controller to another can be simplified and speeded. Not only must an aircraft position be passed from one controller to another but also its identification and intended flight path.

Each of the elements described above is essential if the requirement for expeditious traffic control is to be fulfilled as traffic becomes heavier and heavier.

ELECTRONIC AIDS TO AIR-TRAFFIC CONTROL

64. Communications Devices. The communications system described in a previous section forms the means for the controller to instruct the aircraft and the way in which the pilot of an aircraft can render information as to his position and intent within the air-traffic-control zones, for either approach control or en route control. Because of the time required for a communications sequence to take place, high-speed communications such as described in the previous section, AGACS, or other methods of high-speed communications will become more essential as traffic increases. It is to be remembered that, since the process of air traffic control is essentially a series of actions taken in appreciation of a rate of change of the aircraft situation, the amount of communica-

tions required will increase with the number of aircraft being handled but not in a 1:1 ratio. Obviously, as coordination becomes more complex, with more and more aircraft in a particular approach control zone or in a particular route segment, the amount of communications exchange will increase rapidly and in a relationship much more steep than linear. While the addition of new communications channels helps the situation by providing more communications paths, the amount of work per controller increases with the amount of traffic. His ability to communicate by voice with a number of aircraft is limited not only by his own ability for comprehension of the situation but by the access and time requirements for each communications sequence. Thus, high-speed automatic communications, at least for the exchange of routine information, seems to be an essential as the requirements for expeditious air-traffic control become more and more stringent.

65. Location and Identification Aids. Traditionally, the process of air-traffic control has utilized reports of aircraft over fixes. The "fix" is an aircraft position at a specified point over which an aircraft reports, for air-traffic-control purposes, usually identified by a navigation aid. By reporting aircraft over fixes at various altitudes each aircraft in a control situation is assigned a block of airspace more or less in the form of a cocoon, the cocoon being formed by an altitude layer above and below the aircraft's desired altitude, by a lateral separation between aircraft, usually developed from ground navigation aids, and by longitudinal separation between aircraft in terms of time. In other words, air-traffic control is accomplished by moving the airspace blocks or cocoons in whose center an aircraft travels, by separation of altitude, lateral space, distance, and time. After an aircraft vacates a given fix, another aircraft can be moved into the same block of airspace without danger of conflict. The size of the airspace block depends on the quality of the navigation aids by which an aircraft maintains its position within the block and on the rapidity of the ground controller's appreciation of the rate of change of the momentary situation.

If the controller is provided with positive information as to the position of an aircraft, the separation between aircraft both en route and at an intersection can be substantially reduced. The device which provides the controller information as to the position of aircraft in the vicinity of an airport is the airport surveillance radar.

66. Airport Surveillance Radar. This is an existing electronic equipment designed to detect the presence of aircraft within range of the airport. The position of the aircraft is shown with a high degree of accuracy in range and azimuth. Elevation is not shown.

Airport surveillance radar is probably the most important contribution to the expeditious movement of air traffic since the Second World War. By permitting accurate position information to be displayed to the controller, the utilization of the airspace in the vicinity of an airport is materially increased. For example, at an airway intersection where, without radar, a 10-min period is required before an aircraft is permitted to cross the path of another aircraft, with radar, separations of 1 min are permissible. In the case of an aircraft traveling at 300 mph, this amounts to a difference in the required distance separation of 50 miles when no radar is used and 5 miles when radar is used. Comparable reductions in time and distance separation are attained in the en route arrival and departure situations. The substitution of positive 3-mile separation for the time or altitude separation required in a nonradar operation has permitted a considerable reduction in the interval between successive landings of aircraft on the runway and successive departures of aircraft from the runway. This results in a corresponding reduction of delays of aircraft under high-density traffic conditions.

The airport surveillance radar is an outgrowth of the radar approach and landing system known as GCA developed during the Second World War. The CAA has installed a total of 31 airport surveillance radars in major traffic hubs with plans for additional equipments under way.

67. Long-range Radar. While the airport surveillance radar is an excellent air-traffic-control aid for the approach control zone, it does not provide sufficient range to
FIG. 7. Manner in which radar increases airspace utilization.

permit its use in the en route control of air traffic under instrument flight rules (IFR). To avoid stacking up of aircraft in the vicinity of airports, flow control of air traffic reaching an airport must be instituted while the aircraft are still far from their destination. As an aid toward the control of traffic, the long-range radar promises to provide excellent service as an en route aid as well as approach control aid. Long-range radar is not only useful in the control of air traffic but is also a vital part of our air-defense system. As a result, it is planned that integrated use will be made of long-range radars

for both air-traffic control and air defense, even though not all defense radars are technically and operationally suitable for joint use.

68. Secondary Radar. While the use of radar as an aid to air-traffic control has influenced aviation tremendously the basic radar has one major drawback. Each aircraft looks like every other aircraft, and thus there is almost total anonymity about the blips to the air-traffic controller. Since it is necessary for the controller not only to be aware of an aircraft in a particular location, but also to know the identity, type, and flight plan for that aircraft, identification becomes almost an essential. Secondary radar, or the ATC radar-beacon system, solves the problem of identification of the individual aircraft in air-traffic control.

The secondary radar is an electronic means of detecting and identifying aircraft. Whereas primary radar relies on the reflection or echo of ground-transmitted radar signals from the surface of an aircraft structure, secondary radar utilizes the transmission of radar replies from the aircraft. The ground station sends up a coded interrogation at one frequency (1,030 Mc) to the aircraft. Aircraft equipped with an airborne ATC transponder reply on a different frequency (1,090 Mc) with pulse-coded reply signals. By utilizing between two and eight reply pulses in the reply group, specific binary code identification is attained. By decoding the replies on the ground and displaying symbolic information synchronously with radar echo, specific identification codes, assigned to aircraft by the air-traffic controller, can be displayed in any number of ways on the ground controller's display, thus lending specific identity to the previously anonymous blips. By assigning identification codes either by aircraft type, by route, by holding fix, by altitude, or by any one of many different methods, a considerable amount of information about an aircraft can be transmitted via this identification link, without requiring continuous communications between the aircraft and the traffic-control center. The ATC radar-beacon system has obvious uses also in identification of aircraft for purposes of air defense, and promises to eliminate the need for some of the identification maneuvers now required of aircraft entering air-defense zones within the United States.

The ATC radar-beacon system, in addition to providing the basic identification feature, will reinforce weak primary-radar signal returns from jet fighter and other types of aircraft having small reflection areas. It will serve the further function of providing strong returns under conditions of heavy precipitation which render the present-day S-band surveillance radar system virtually useless. It is the CAA plan to install ground ATC interrogators as an adjunct to all airport surveillance and long-range radars, including a portion of the military radars planned for joint air-defense–air-traffic-control use.

69. Precision Approach Radar (PAR). As an aid in the final approach of aircraft to land, the precision approach radar is a system designed to monitor the progress of an aircraft to the instrument runway and to present the information to the controller in the tower with a high degree of accuracy. Distance, bearing, and elevation above ground are presented continuously on the face of the radar scope. PAR in conjunction with airport surveillance radar constitutes the military ground-controlled approach (GCA) whereby a controller can "talk" the pilot down to a successful landing. In civil use where ILS is widely used and where the pilot himself makes his landing on the basis of information from the electronic glide-slope and localizer beams, the PAR facility is used primarily by the air-traffic-control agency to monitor approaches and to warn the pilot if he is too low, too high, or off the center line of the instrument runway.

PAR equipment is an outgrowth of the military radar developments during the Second World War. A total of 10 precision approach radars have been installed at major traffic hubs as of June 30, 1955.

Since PAR is used only in the approach area leading to the instrument runway, it scans only a small portion of the total airspace around an airport. Present-day precision approach radars look only 20 deg in azimuth and 6 deg in elevation. These triangular segments are expanded in presentation and occupy almost the full area of

the radar controllers' display. With PAR operated in the 3-cm band, the position of an approaching aircraft may be determined within about 20 ft of elevation, 40 ft in azimuth, and 300 ft in range when the aircraft is a mile from the end of the runway.

70. Airport Surface-detection Equipment (ASDE). As our airports grow larger and the runways longer, air-traffic control after touchdown becomes an important part of the air-traffic-control job. Accurate information to the tower and operator as to the progress of an aircraft along the runway during bad weather can permit more frequent landings and take-offs than if no visual surveillance were possible. It is an acute problem at high-density airports because runways and taxi strips which may be nearly out of vision of the controller even on clear days must be immediately known clear if traffic is to be moved without serious delays.

ASDE is a radar usually operated in *K* band which looks directly at the airport and has very short range. Its only purpose is to display traffic on the ground on runways or taxi strips. The provision of ASDE is of primary use in large heavy-traffic metropolitan airports, and it is planned that approximately 20 locations will be equipped within the next several years.

ANALYSIS OF POSITION AND PROGRESS OF AIRCRAFT

By the use of navigation aids for the aircraft and information on position and progress of the aircraft made available to the ground controller through radar, secondary radar, and other devices, we can provide nearly all the tools for the control of air traffic. The only problem is that in a high-traffic situation information comes to the controller so fast and from so many different sources that rapid analysis of the constantly changing complex situation is a formidable task. Therefore, it will become necessary not only to automatize the development of information on aircraft position and progress, but also to automatize the computations which must be accomplished before a controller can make decisions in the traffic-control situation.

71. Computer Applications. A large number of developments, both military and civil, are working toward the goal of simplifying the controller's task. The work is predominantly in the field of air-traffic-control computers which store and compute the information about specific aircraft and their progress. By feeding into the computer the present position of all aircraft under control, their speed, and their course, a computer can store this information and compute the situation that will exist a few seconds or a few minutes later. Depending on the sophistication of the computer and on the method of feeding data to it, the computer either can store the information and give it back to the controller on demand or can continually compute the impending situation by means of flight plans fed to it or by continuous information fed to it from radar sources or by the controller himself, and thus warn of impending conflicts as well as provide the controller with instructions for various aircraft to provide satisfactory control. It is apparent that, while the individual acts of a computer for traffic control, for example, are relatively simple arithmetic computations, the traffic-handling capacity required of such a computer and the absolute reliability required make automation of the traffic-control process a complex procedure.

The possibilities of computers improving our air-traffic-control systems are virtually limitless, and discussion of the many detailed systems is beyond the scope of this book. It may be useful, however, to suggest briefly two areas in which considerable work is going forward.

One device is a storage system for flight-plan data, basically a storage drum, which is fed information from teletype-machine sources, and can serve to store flight plans which might have been filed by the aircraft which are to come under control in a particular control area. Fed flight-plan information and progress reports periodically, the equipment can advise the controller, on the basis of time, of traffic which will come into his control at a particular time and in a particular manner. An extension of this arrangement would feed flight-plan corrections into the drum as they are received, so that only up-to-date information is displayed, and add computers which would follow flight progress automatically and warn of impending conflicts.

This type of traffic-control-coordinating equipment is only one of a number of types intended to simplify the controller's task by automatically providing him with information which he would normally compute laboriously or sort out of a maze of individual communications.

On the more complex side of the picture is a system developed for military use called the semiautomatic ground environment (SAGE). This system, while not specifically intended for civil air-traffic control, illustrates a class of system where such control might be automatized almost completely. In this system, the basic source of information is a series of ground radars. The ground equipment automatically performs various computations for the purpose of guiding interceptor aircraft and in aiming other weapons. It is capable of combining the coordinates of several radar sets one with another into a common display system and it acts as a communication network between the operators.

This system is intended to provide a central machine with a large and rapidly functioning memory whose job would be to keep track of all aircraft. All data are sent to this machine automatically, and the function of men in the data-transmission process would not be to transmit data but to inhibit the data when they obviously become false. This system requires not only a number of radars to cover a particular area but a large network of communications to feed the automatic machine.

In the study of air-traffic control and the electronic devices, from radars to computers, which might be used in effecting air-traffic control, it has become apparent that we have at our disposal the scientific tools to do almost any computation and the storage of any information we might see fit. One important consideration, however, is that of economics, for while nearly any job can be done, the complexity and expense of providing such service may readily become prohibitive and thus unattainable economically.

A further consideration in the automation of an air-traffic-control system which has troubled system designers for many years is the basic question of reliability of automatic systems. While some argue that an automatic system is not subject to human error, and should be far more reliable than the equivalent human controllers, others point out that no automatic system, no matter how sophisticated, can exercise judgment in emergency situations. The latter group feels, therefore, that while we should make every possible use of automatic devices to simplify the job of the air-traffic controller, we should always let the decision-making authority remain with the human controller who has the judgment to take over the situation where the computing machinery has failed.

AIR-TRAFFIC CONTROL AND THE VARIOUS CLASSES OF AIRCRAFT OPERATORS

In the previous sections of this discussion, a number of different air-borne equipments have been discussed. It is important to note that the Federal airways air-traffic-control system must accommodate not only the aircraft equipped with the latest and best of air-borne aids but must also take care of the aircraft which cannot, for any of many reasons, carry sophisticated equipment. Whereas modern airliners might carry all possible equipment which could be useful in air-traffic control, many private aircraft will have to make do with a minimum of air-borne equipment. Thus, any modern air-traffic-control system must be capable of accommodating all users of the airways, those with a minimum amount of equipment and those with complex and sophisticated electronic installations.

THE PECULIARITIES OF AIR-BORNE ELECTRONICS EQUIPMENT

72. Reliability. Electronic equipment in aircraft must be reliable. Frequent failures may abort an expensive and important mission. Yet while reliability and accuracy in air-borne electronic equipment are essential, the environment aboard an aircraft places nearly every handicap on the attainment of this goal. We require lightweight and small-sized electronic equipment to make it economical to carry, yet we

expect extreme ruggedness from the resulting equipment. The equipment must withstand the shock and vibration encountered during flight and during ground transportation over rough terrain. We subject the equipment to considerable variations in voltage and frequency. We expect the equipment to operate under a very wide range of temperatures and a wide range of altitudes. With all this we expect long-term stability and need of only infrequent checking or calibration of the equipment.

73. Weight, Size, and Cost. There are generally three categories of air-borne electronic equipment. The first of these is the equipment used aboard itinerant aircraft, generally in the smaller single-engine or light twin-engine types. In this type of equipment, size and weight are at a premium, but perhaps cost is even more important. In addition to these restrictions, the small itinerant aircraft usually has only a limited amount of electrical power available, so that low power drain is an additional requirement. Further, the economic situation of many itinerant aircraft operators is such that maintenance of equipment will be often done primarily when something has gone wrong, so that emphasis must be placed on extreme reliability and deteriorative failures or time-dependent loss of calibration must be avoided. Aboard the modern itinerant aircraft, the first requirement is for communications equipment, with simple navigation equipment closely following in importance. Low-cost versions of communications equipment and of some navigation devices have been developed for light-plane users.

At the other end of the scale in complexity and cost is the air-borne equipment installed on military aircraft. Subject to much greater rigors in terms of altitude, shock, and vibration, etc., than light-plane equipment, tremendously greater demands are also made upon it. Because the weight and amount of electronic equipment directly affect the performance and combat capability of military aircraft, extreme emphasis must be placed on miniaturization. It is in the military fields that the new frontiers must be opened not only in the miniaturization of the equipment but also in providing reliable performance. Military aviation electronics equipment must assure long-term reliability and stability for big, long-range aircraft, and must be equally reliable in tiny fighter aircraft where there is little space for the pilot, much less for bulky electronic equipment.

Military electronic equipment is often located in nonpressurized areas and much of the gear must be built in pressurized containers to withstand altitudes up to 75,000 ft, as well as extreme variations in temperature, and not only the shock and vibration of normal aircraft maneuvers but also that resulting from the firing of weapons.

The third category of air-borne electronic equipment is that used by air-carrier aircraft. In this mode of operation size and weight are obviously also important but to a somewhat lesser degree than reliability. To assure reliability of air-borne electronic equipment used in air-carrier service, most devices are carried in duplicate and independent systems are provided to permit easy switching from one to another in the event of failure. Electronic equipment aboard air-carrier aircraft is usually located in a pressurized area near the crew compartment so that it must withstand neither the rigors of extreme altitude variation nor extreme temperature variation often required of military equipment.

On the other hand, whereas military electronic equipment is usually intended to have a useful operating life in the vicinity of 1,000 hr, air-line equipment is required to operate for much longer periods. This disparity arises from the fact that military aircraft, intended for performance of a particular mission in wartime or the training for that particular mission in peacetime, are of necessity in a waiting status a high percentage of time. The air-carrier aircraft, and the military transport service as well, are required to operate 9 to 12 hr per day every day so that 1,000 hr of operating life is usually accumulated in a period of 3 to 4 months. Equipment carried aboard air carriers is normally expected to operate satisfactorily for a minimum of 1,000 hr and usually 1,600 to 2,000 hr between scheduled removals for maintenance and service.

The weight of electronic equipment is a vital concern to the designer and user of

modern aircraft and thus great emphasis is placed on lightweight reliable air-borne electronic equipment. In a modern air-carrier aircraft, there are approximately 26 radio or electronic systems with hundreds of switches, control knobs, push buttons, indicating instruments, etc. This requires approximately 55 cu ft of space and approximately 2,400 lb for the total installation. Each pound of electronic equipment not only increases the basic cost of the aircraft but reduces its payload capacity and increases its cost of operation. Therefore, great attention must be paid to the reduction of weight wherever possible, but without a reduction in over-all reliability. Unreliability can cost many times increased operating cost due to the weight of the electronic equipment.

74. Aircraft Antennas. Whereas the designer of radio equipment or electronic equipment for ground or ship-borne use is usually little concerned with the aerodynamic drag introduced by a fixed antenna, this problem is of paramount importance in design of antennas for aircraft. While the aerodynamic problem of where to locate antennas has been present since the first radio went aboard an aircraft, the problem is severely aggravated on the new high-performance aircraft types. As an example, the air-borne ADF requires two antennas, a loop and a sense antenna. The loop antenna was, and on many aircraft still is, housed in a football-shaped housing which protrudes from the aircraft belly. The sense antenna is a wire antenna suspended away from the aircraft skin on two masts. While on present-day aircraft these antennas cause aerodynamic drag, this drag can be justified on the basis of the performance attained from the ADF system. On high-performance aircraft the costs in terms of aerodynamic drag and loss of aircraft performance make the old type of antenna arrangement totally unusable. Instead, a loop is used which is essentially submerged in the belly of the aircraft, and a sense antenna which is also nearly submerged and is flush with the skin of the aircraft. Quite naturally, as the aerodynamic drag imposed by the ADF antenna system is thus so reduced, the performance may also be reduced, since submerged radiators are often not so good as antennas with more effective electrical height. It has become necessary to improve the electronic equipment itself to the point where the equipment can compensate for the reduced performance received from the antennas.

One other case of interest is the h-f communications-system antenna. For the h-f antenna on conventional present-day aircraft, a long wire is normally used, suspended well away from the aircraft and usually extending from the vertical stabilizer well forward to the nose of the aircraft. On high-performance aircraft, this kind of an antenna may be unacceptable. In its place designers are using an insulated section of either the wing or the vertical stabilizer to serve as an antenna. This is accomplished by electrically isolating the tip of the vertical stabilizer, for example, from the rest of the aircraft and exciting this isolated section.

The operational characteristics of an aircraft at a given speed affect the determination of the tolerable amount of drag due to an antenna. On new jet air-transport aircraft, 1 sq ft of parasitic drag area (roughly equivalent to the area of a flat plate producing an equivalent drag) is equivalent to 1,200 lb of additional weight. The submerged type of antenna, even if it provides good electrical performance, cannot be judged on this criterion alone. In pressurized aircraft intended to travel at high speeds, the submersion of an antenna generally requires considerable structural beefing in the vicinity of the antenna to preserve the integrity of the air frame; thus even the submerged antennas cost a great deal in actual weight. For each instance an analysis must be made to determine the relationship of the structural weight of a submerged antenna against the aerodynamic drag (and thus effective weight) of an antenna which protrudes from the aircraft.

75. Electrical Power. All aircraft are limited in the amount of electrical power available for electronic equipment. Economy in the utilization of electrical power is a requirement for all types of aircraft.

The power sources aboard modern aircraft can be roughly divided into three general types:

A d-c supply is usually 6 or 12 volts for small itinerant aircraft, 27.5 volts nominal for air-carrier and military aircraft. The d-c power supply in most older transport aircraft is the basic source of electrical power and it is generated from an engine-driven generator. Voltage regulation of the 27.5-volt supply of +10 and −20 per cent is normal. Where d.c. is the only source of basic power aboard the aircraft, inverters are widely used to provide the necessary a.c., although many air-borne radio-equipment types, used in both air-carrier and itinerant service, utilize dynamotors and (particularly in the itinerant service) vibrator power supplies to supply high voltage.

The a-c supply in a basically d-c airplane is usually obtained from a 400-cps, 115-volt, three-phase, one-side-grounded inverter. Power from this type of machine may vary in voltage as much as ±10 per cent from the nominal 115 volts and the frequency may vary 20 cps. On some present-day military aircraft, a-c power is available also from inverters which are not regulated to a specific frequency and which may vary from 300 to 1,000 cps, with voltage variations of ±10 per cent.

On new transports and many new military aircraft the power sources are predominantly 400-cps a-c supplies from engine-driven alternators. Considerable weight savings are attained in this type of basic electrical-power supply and close control of frequency and voltage will be available to the air-borne electronic equipment. In the a-c aircraft, the d-c supply, which will continue to be used widely for operation of control circuitry and for some transistor equipment, will be of somewhat poorer quality. This power will be obtained from a transformer-rectifier system with only limited voltage regulation.

With this change in the power-supply concept aboard some military and new air-carrier aircraft, it becomes a requirement for air-borne electronic equipment to provide considerable flexibility in power-supply arrangement. Electronic equipment designed for a particular purpose must usually be adaptable to either a basically a-c or a basically d-c airplane. Both varieties of aircraft will be in operation for many years.

76. Interference and Interference Reduction. The designer of air-borne electronic equipment must accept as one of his design problems the fact that air-borne electronic equipment must live in an electrical environment which often produces interference. He must consider these conditions and design the equipment to perform its normal functions in the presence of interference.

Interference may be incurred from atmospheric disturbances, man-made noise (such as from aircraft electrical equipment or other radio equipment in the aircraft or received at the antenna), or inherent tube noise. An effort to eliminate the effects of interference must be based on where the interference originates. Some forms of interference will originate within the equipment itself or will result directly from other equipment or accessories in or around the aircraft. Other types of interference will be encountered which are due exclusively to effects occurring outside of and at a distance from the aircraft.

The designer of an aircraft electrical system has the responsibility for assuring that an aircraft is essentially noiseless electrically. This means in theory that the aircraft is designed to suppress ignition noise and to assure that power lines circulating within the aircraft do not carry radio and electrical noise. It is difficult for the aircraft designer to provide an aircraft which is completely noise-free, and it is therefore necessary that the electronic equipment be designed to be tolerant of considerable noise and ripple on power control entering the equipment.

One major cause of interference, particularly in the low- and medium-frequency regions, is atmospheric interference due to *precipitation static*. Precipitation static is radio interference experienced when the flight path of the aircraft is such that disruptive static discharges are caused from the aircraft. Precipitation static is developed by flying through snow or dust storms, raindrops, thunderstorms, ice crystals, etc. The elimination of sharp edges or pointed protuberances and the bonding of separated parts of the aircraft structure help to reduce the precipitation-static problem. The use of discharge wicks and improved antenna wire and insulators all appear to help the problem somewhat. Although the smooth external characteristics of high-speed

modern aircraft with essentially dragless antennas should make them more immune to interference from precipitation static, the use of dielectric materials such as Plexiglas and Fiberglas appears to cause serious new precipitation-static effects. Plastic bubble canopies on fighter aircraft appear to be serious offenders in causing precipitation static. While developments go forward toward cleaning up the aircraft to prevent fast static discharges, other developments are working toward the elimination of the effects of the static by circuitry methods, for example, by disabling the air-borne receivers during periods of heavy discharges.

CHAPTER 26

AVIGATION ELECTRONICS

By Anthony Casabona*

1. Introduction. The success of any transportation system depends to a large measure upon the rigorous maintenance of safe scheduled operation. During the last decade the airplane has become a most important factor in transportation and it is recognized that radio is an indispensable tool in maintaining and furthering the aviation transport industry. Today the scheduled air lines of the United States average hundreds of millions of miles annually, with air mail and air express being carried in large volumes. In addition, military, business, and private flying has increased at a rapid rate. These factors, coupled with the use of high-speed modern aircraft, have created many problems in the safe conduct of air operations. Such operations are conducted daily around the world and would be virtually impossible without modern radio aids.

Radio provides aviation with communication, navigation during all phases of flight, traffic control, collision-warning services, and airport-surface control. From the time that the first piece of radio equipment was installed on a transport airplane the ultimate goal has been the unification of these basic functions into an integrated system directed toward the continuous and safe movement of air traffic. As the operational problems of air transport have become progressively more complex, there has been a gradual shift of responsibility for aircraft control from the individual pilot to a ground controller. This transition can be expected to continue as air traffic and speeds increase.

In the division of responsibility between ground controllers and crews of aircraft, the ground controllers must be aware of the flight plan to be followed and must make frequent checks of the degree of adherence to the prescribed plan. In the present state of the art, the air crew must be given sufficient information to carry out the prescribed plan with minimum reference to the ground controllers. Ultimately, it appears necessary to by-pass the human navigator and to apply the navigational intelligence directly to the controls of the aircraft. In such a system, the air crew should have means for correcting the flight of the craft if it does not adhere to the control plan, or for deviating from the plan in case of emergency. The ground controller must have a continuous display of position of each craft in flight, with means for issuing control signals to conform to existing traffic requirements and flight conditions. Automatic ground computers, and associated automatic pictorial display of the monitored data, must form an important part of any efficient traffic-control system. Regardless of the computation equipment required to process the data, the input data themselves must be collected by one radio means or another. Accordingly, this has become an important additional requirement on the organization of the basic radio services.

2. Organization of Civil-aviation Radio Facilities of the United States. The Civil Aeronautics Administration (CAA) of the U.S. Department of Commerce is the

* International Telephone and Telegraph Laboratories, formerly Federal Telecommunications Laboratories. The author wishes to express his gratitude to many individuals, and to the management, of the ITT Laboratories for their assistance and cooperation during the writing of this material; to Richard P. Battle, Deputy Chief, Facilities Division of the Civil Aeronautic Administration, New York International Airport, for his review and valuable suggestions concerning the information on CAA facilities; and particularly to Brigadier General Peter C. Sandretto, Vice President and Technical Director of the ITT Laboratories, for his advice and the use of material from his book "Electronic Avigation Engineering."

government organization responsible for the installation, maintenance, and operation of civil-aviation radio facilities, for research and development leading to their improvement, and for the dissemination of information. Installation and maintenance functions, which include the planning, design, construction, installation, and improvement of air-navigational aids, are carried on by the Air Navigation Facilities Service; the actual operation of facilities is carried out by the Airways Operations Service; and research and development activities are conducted by the Technical Development Service.

Airway facilities, exclusive of communications, directly operated by the CAA as of Jan. 1, 1956, are listed in Table 1. A small portion of the VOR, the Federal airways system, is shown in Fig. 1.

Table 1. Extent of CAA Facilities for Air Navigation and Control

Item	Number
1. Number of facilities, as of Jan. 1, 1956	
a. Mileage of civil airways	
(1) Total:	
V-h-f	79,500
L-f/m-f	69,770
(2) Under traffic control	44,057
(3) Oceanic routes	14,400
b. Air-navigation radio aids	
(1) Adcock ranges (RA and MRA)	344
(2) Loop ranges (RL, MRL, and ML)	
(3) V-h-f ranges (VOR)	419
(4) VAR	6
(5) H-type markers (radio beacons on airways)	175
(6) K-type markers (compass locators)	42
(7) Fan markers (full-powered)	236
(8) Fan markers (low-powered)	28
(9) Instrument-landing system (ILS)	157
(10) Approach-search radar (ASR)	31
(11) Precision-approach radar (PAR)	10
(12) Distance-measuring equipment (DME)	234*
c. Traffic control	
(1) Combined station tower	75
(2) Airport traffic-control towers	100
(3) Airway traffic-control centers	31
2. Airway light beacons	842

* DME of this type has been decommissioned in accordance with the Air Coordinating Committee's decision of 1956 and will be replaced by a Tacan-type DME, often referred to as DMET. (See Sec. 7.)

Other agencies of the government have duties requiring the operation of radio facilities which can be utilized by civil aviation. Among these are the Army, Navy, Coast Guard, and the Federal Communications Commission. As a service to pilots, CAA maintains close liaison with these facilities, disseminates up-to-date information on their status or on sources of information regarding their status, and, where needed, establishes services to facilitate their use.

3. Information Sources. Current information on air-navigation radio aids is given in the following publications:

Flight Information Manual. U.S. Department of Commerce, CAA, Office of Aviation Information. Issued semiannually. Includes air-traffic control and communications procedures, instrument-approach procedures, direction-finding station data, airport and radio-facility indexes, foreign-entry and flight requirements, and radio call letters and frequencies.

Airman's Guide. U.S. Department of Commerce, CAA, Office of Civil Aviation. Issued biweekly. Includes information on new facilities, facility changes, and notice to airmen on temporary conditions, such as airway construction or inoperability of facilities.

Radio-facility Charts. U.S. Department of Commerce Coast and Geodetic Survey. Revised weekly. Contains 42 separate charts providing complete radio information to facilitate the planning and execution of cross-country flights in the United States. Shows all radio-facility data with detailed tabulations of all radio stations in operation, classified as to aids to navigation and control towers.

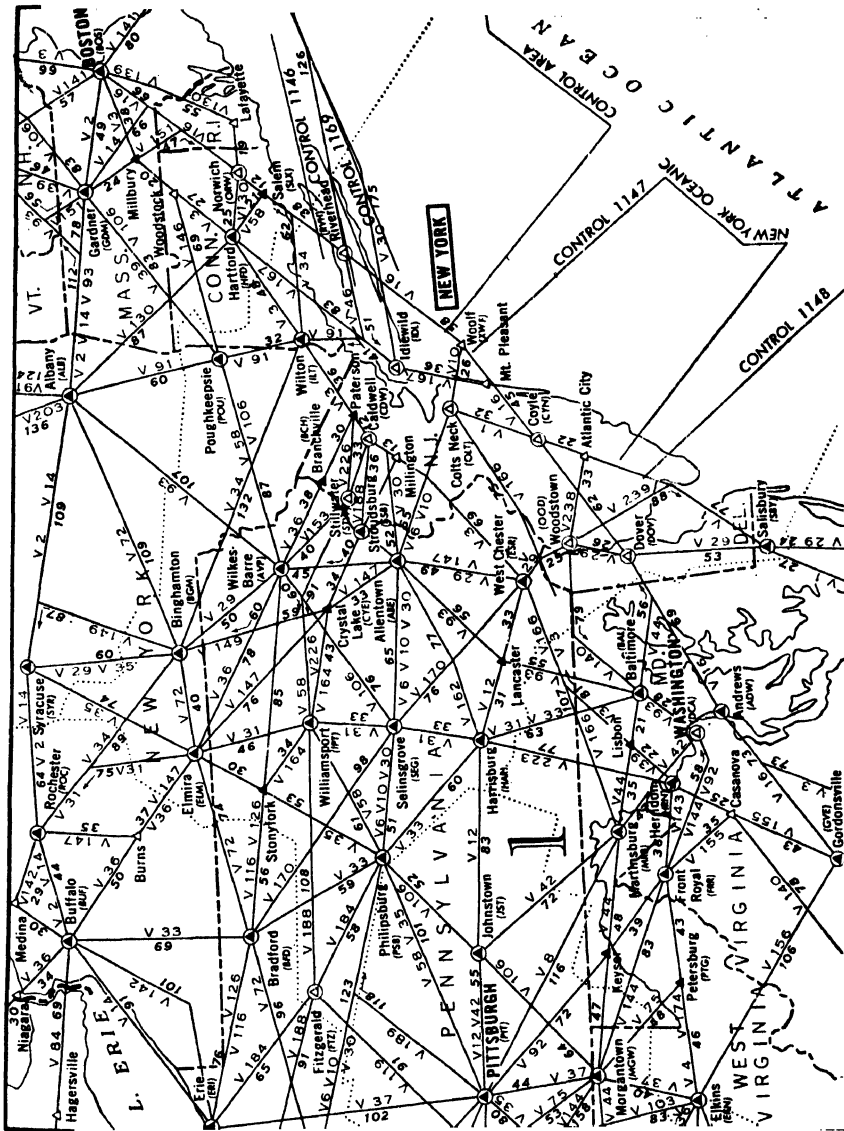
Catalogue of Loran Charts and Service Areas. U.S. Navy Department Hydrographic Office. H.O. Pub. 1-L. Includes description of loran system, discussion of factors affecting


FIG. 1. A portion of the VOR airway system. (*Courtesy of CAA.*)

accuracy, shows ground-wave and sky-wave coverage, and presents a chart index of loran service in the Atlantic and Pacific Oceans.

Army Air Forces Radio-facility Charts. Headquarters, Air Materiel Command, Wright Field, Dayton, Ohio. Issued monthly. Furnishes data and charts for use by Air Force pilots; shows how military aircraft utilize virtually the same radio-navigational facilities as do the civil aircraft.

United States government facilities comprise many diverse types of equipment. The following brief descriptions of these facilities are intended to explain their functions; technical details will be presented in subsequent sections.

4. Radio Ranges. Radio-range stations provide radio-defined courses for delineation of lines of flight during restricted-visibility conditions and over-the-top operations when visual contact with the ground is impossible.

The first type applied to the airways was the l-f directional, four-course, aural radio range. Some 344 are still in use. These operate within the band 200 to 400 kc, with a modulation frequency of 1,020 cps. Each range has four courses, produced by the alternate interlocked Morse-code keying of two figure-of-eight patterns, one N and the other A, directed at approximately right angles to each other, the exact direction of each course being that which will best serve the airway and/or airport. Ranges are normally located within 2 to 4 miles of an airport, at least one course being aligned in such a manner as to facilitate instrument approach to same.

The position of a course is determined by comparing the relative strength of the signals N and A, the proximity of the course being indicated by approaching equality of these two signals. Exactly on course, the interlocking of the two signals produces a steady monotone (1,020 cps), interrupted only for station identification. The latter, consisting of a two- or three-letter combination, is transmitted twice every 35 sec, first in the N quadrant and then in the A quadrant.

Voice transmissions are made on the range frequency unless otherwise indicated by the inclusion of the letter W in the station designation.

These l-f directional ranges can be further classified by type of radiator utilized and by power output as follows:

Tower Radiators. Five steel towers approximately 130 ft in height, four forming a square and one in the center, are utilized for the following designations:

RA, power output between 150 and 400 watts, usable distance 65 to 100 miles
MRA, power output between 50 and 150 watts, usable distance 40 to 75 miles

Loop Radiators. Two crossed, vertical loops mounted on five poles approximately 50 ft in height, four poles forming a square and one in the center, are utilized for the following designations:

RL, power output between 150 and 400 watts, usable distance 50 to 75 miles
MRL, power output between 50 and 150 watts, usable distance 30 to 55 miles
ML, power output less than 50 watts, usable distance 20 to 40 miles

5. V-h-f Directional Range (VAR). This is a two-course visual, two-course aural range with simultaneous voice feature operating within the band of 112 to 118 Mc. The power output is approximately 200 watts, and the usable distance is limited by line of sight, depending upon the altitude of the aircraft and the terrain, with an upper limit of about 200 miles at very high altitudes. The radiators employed are small and closely spaced, being located in a small building mounted on a tower 30 to 60 ft in height; a counterpoise approximately 35 ft in diameter is also mounted on the tower.

The visual courses of VAR are 180 deg apart and are created by the overlapping of two field patterns essentially cardioid in shape, one modulated at 90 cps and the other at 150 cps. An electrical indicating zero-center instrument, actuated by a receiver designed for the purpose, is utilized in the aircraft to locate and fly the courses. This is accomplished by comparing the relative strengths of the two opposite sectors. The indicating pointer, or needle, is centered (vertically) on the instrument scale when the aircraft is exactly on course. Full-scale deflection of the needle will occur at approximately 10 deg off course.

The aural courses of VAR are also 180 deg apart and are located at right angles to the visual courses. The aural courses are produced by the alternate interlocked Morse-code keying of the letters N and A in a manner similar to that of the l-f directional range, except that the field patterns are like those utilized for the visual courses of VAR. The modulation frequency of the aural signal is 1,020 cps, and like the l-f directional ranges, the aural signal is interrupted approximately twice a minute for transmission of the station identification. The orientation of the N and A sectors with respect to the visual courses is always the same; *i.e.*, N will be on the east leg of a visual east-west course or on the north leg of a visual north-south course.

6. Omnidirectional Radio Range (VOR). The omnidirectional radio range radiates a signal which, through the use of special receiving equipment, may be utilized to establish a visual course in any radial direction with respect to the transmitting station. Such a station may be considered to have an indefinite number of flyable courses. It was developed to provide the type of service required by the concept of the universal airway. An "azimuth-selector" dial enables the pilot to select a course along any direction toward or away from the range station, special means being provided to resolve ambiguity. The pilot follows the selected course by keeping the pointer of the indicating instrument centered (vertically).

This facility may be used for determining the true bearing of the aircraft with respect to the station by tuning in the station and adjusting the azimuth selector so that the instrument pointer centers, *i.e.*, reads on course. The selector dial then presents the desired bearing reading. An "azimuth indicator," operating independently of the selector dial and course indicator and giving direct-bearing information, is also available. Bearings obtained from two or more stations will enable the pilot to determine his geographic position.

VOR operates within the band of 112 to 118 Mc. In appearance, power output, and usable distance the VOR station is similar to the VAR station.

The station identification of the VOR type is transmitted intermittently on the carrier, utilizing a 1,020-cps keyed tone, except during voice transmissions. Simultaneous voice transmissions are made on the range frequency of all VOR stations unless otherwise designated by inclusion of the letter W in the station-type designation.

7. Distance-measuring Equipment (DME).* This device, an adaptation of wartime radar, enables the pilot to determine at all times his distance from the transmitting station. The air-borne equipment comprises a transmitter and receiver, the former unit transmitting short high-amplitude pulses approximately 150 times per sec. These pulses are received at the ground station, which likewise comprises a transmitter and receiver, the receiver being tuned to the frequency of the air-borne transmitter. Each time a pulse is received on the ground, the associated transmitter is immediately triggered and sends a pulse reply. When this pulse from the ground is received by the aircraft, circuits in the air-borne equipment measure the time interval between the interrogating pulse originated by the aircraft and the reply received from the "transponder" on the ground. This time is indicated on a meter calibrated in miles.

The air-borne equipment consists of a transmitter, receiver, indicator meter, and associated gear. The ground equipment consists essentially of a receiver and transmitter. Current equipment of this type operates in a band centered at 1,000 Mc. In operation, a beacon is capable of replying to as many as 100 air-borne units at the same time.

The ideal in navigation of aircraft under instrument conditions is to obtain continuous direct readings of distance and direction from one or more ground points. The omnidirectional beacon provides a solution of the problem of direction; the solution of the problem of distance measuring can be achieved by the installation and use of DME. The system provides flight paths especially convenient for accurate manual or automatic following: (1) along radial courses to or from the ground stations; (2) along circular orbits of any radius about the ground stations; and (3), with an R/θ computer added, along any straight-line path offset with respect to the ground stations.

8. Loran. This is a long-range navigation system developed during the war and widely adopted throughout the world. It operates on the following principles: radio

* DME of this type has been decommissioned in accordance with the Air Coordinating Committee's decision of 1956 and will be replaced by a Tacan-type DME, often referred to as DMET. DMET constitutes one component signal of the VORTAC system. As planned, a complete VORTAC installation will consist of co-located VOR and Tacan equipments, thereby providing bearing from either the VOR or Tacan as well as distance (DMET) from Tacan.

DME and DMET utilize the same basic principles, the main difference being that DME is pulse-multiplexed to provide the required number of channels whereas DMET operates with clear-frequency channels.

As of 1958, the CAA has scheduled the implementation of a complete VORTAC environment to cover the airway system of the United States.

signals consisting of accurately synchronized short pulses (80 μsec) are broadcast from a pair of special transmitting stations (a "master" and a "slave"), separated by from 200 to 400 miles and operating on a common frequency within the band 1,800 to 2,000 kc. Each pair of stations comprises a loran facility, or "rate." These signals are received aboard the ship or aircraft on a special receiver, and the difference in times of arrival is measured on a special indicator. This measured time difference is utilized to determine directly, from special loran tables or charts, a line of position which (neglecting the oblate curvature of the earth's surface) is a hyperbola with the two transmitting stations of the loran pair as foci. Two intersecting lines of position, determined from two properly selected loran rates, are required to obtain a loran fix.

A number of loran rates operate on the same radio frequency, but the pulse-recurrence rate differs for each facility. By setting the receiving equipment for the proper frequency and recurrence rate, the navigator is assured of the identification of the facility utilized.

L-f loran is an adaptation of loran at lower frequencies, primarily to increase the range of useful operation. L-f loran has had successful operational service in central and northern Canada on a frequency of 180 kc, and experiments have been conducted on still lower frequencies. One method of pulse matching, called "cycle matching," affords unusual possibilities of accuracy and will be described in detail in a later section.

9. Marker Beacons. Radio-marker-beacon stations of two essentially different classes, v-h-f and l-f, are located along the civil airways to supplement the radio-range system.

V-h-f markers operate on 75 Mc and include the following types:

Station location marker, designation Z. Serves to locate positively the l-f/m-f range station with which it is identified. Nominal power output 5 watts, unkeyed, 3,000 cps modulation, vertical-cone radiation pattern.

Fan marker, designation FM. Serves to furnish aircraft with a check as to progress along airways, to mark junction of two radio-range courses, to designate "hold-over" point along airport approach 10 to 20 miles from airport, or to mark obstructions. Nominal power output 100 watts, keyed for identification, 3,000 cps modulation, fan-shaped radiation pattern extending (at 1,000 ft altitude) 2 to 4 miles along the range course and 12 miles across the course.

Low-power versions of the fan marker, designation LFM. Nominal power output 5 watts or less; used for special purposes such as for "let-down" along a radio-range course. The lower power is required for installations closer than 8 miles to an airport to reduce interference with Z marker.

L-f markers are nondirectional radio beacons operating in the band 200 to 400 kc and serving principally for use with automatic direction finders (ADF) aboard the aircraft. Station identification, utilizing a 1,020-cps keyed tone, is transmitted intermittently on the carrier. The several types are:

Type HH. 2,000 watts or greater.

Type H. Power output 50 watts or greater; voice-transmission feature unless designation is followed by letter W; operates continuously.

Type MH. Power output less than 50 watts; operates on request, usable range 25 miles.

10. Instrument-landing System (ILS). This was developed to enable properly equipped aircraft to navigate to a safe landing during poor weather conditions without visual reference to the ground. It serves also to reduce the length of time aircraft must be held aloft, during periods of congestion, by speeding up instrument approaches and landings.

A standard instrument-landing system ordinarily consists of a localizer unit (LO), a glide-path unit (GP), and two position markers, each with a homing beacon, designated as "outer marker" (OM), and "middle marker" (MM). In some cases, the homing beacon at the middle marker is omitted.

The *localizer unit* provides a course for horizontal guidance. It is similar to a two-

course v-h-f radio range aligned with the direction of approach. It operates in the band 108.3 to 110.3 Mc, with a maximum power output of 200 watts, and is of the "equisignal" type. It actuates the vertical pointer of the cross-pointer instrument on the instrument panel of the aircraft, thereby providing continuous indication of the lateral position of the aircraft with respect to the approach course. A simultaneous voice feature, for use by the airport controller, is provided on the localizer, together with station-identification keying when voice transmissions are not being made.

The *glide-path unit* provides an equisignal course in the vertical plane containing the approach course and inclined at an angle of 2 to 4 deg with the horizontal as measured from the point of contact. It actuates the horizontal pointer on the aircraft cross pointer and provides continuous indication of the vertical position of the aircraft with respect to the desired "let-down" course. It operates in the band 332.6 to 335.0 Mc with a maximum power output of 20 watts.

Marker beacons are of the low-power v-h-f fan-marker types operating on 75 Mc, with power output of 2 watts. They are tone-modulated and identification-keyed, and may be identified aurally or by lights on the instrument panel of the aircraft. The fan-shaped pattern is directed vertically upward with the fan at right angles to the approach course. The outer-marker modulation frequency is 400 cps and its identification signal consists of 2 dashes per second. The middle-marker modulation frequency is 1,300 cps and it is keyed continuously with alternate dots and dashes. The two markers are located along the approach course, as follows: outer marker, 4 to 7 miles from the approach end of the runway and within 150 ft of the runway center line extended; middle marker, 3,500 ft (±250 ft) from the approach end and within 50 ft of the runway center line.

Homing beacons (type K) are nondirectional transmitting stations in the band 200 to 400 kc, with power output of 25 watts, and operate continuously. They provide signals for automatic radio direction finders aboard the aircraft and thus furnish means for determining the heading of the aircraft with respect to the desired approach course.

Some 157 ILS installations were in operation in the United States as of January, 1956.

11. Ground-controlled-approach System (GCA). Developed by the armed services during the war, some 31 (PAR and ASR) CAA GCA installations were available to civil aircraft as of January, 1956, either on a continuous or on an emergency (30-min notice) basis. The GCA system is a specially developed combination of search and precision scan radar units which permit its operators to "talk the airplane down" to the point of contact on the airport surface. Only the regular flight instruments and communications equipment are needed on the aircraft.

In the wartime version, the GCA station is placed 500 ft to the side of the runway. A 10-cm search radar scans a 35-mile area around the airport, and its operator directs pilots of inbound aircraft to the approach area at correct altitude. This area is about 6 miles from the approach end of the runway.

Two precision 3-cm radar beams scan the approach sector in azimuth and elevation. These give the ground operators precision measurements of distance and lateral and vertical displacement of the aircraft. By proper voice instructions to the pilot, the aircraft is controlled by the ground operators to follow an approach path corresponding to a line drawn on the radar scope maps.

More recent versions of GCA, improved to conform more closely to civil-aviation requirements, employ a three-dimensional scope with the information remotely indicated in the airport control tower. This eliminates the need for coordination between a number of operators and provides for control of all traffic by the traffic-control tower.

Because civil aircraft may not be able to receive the voice transmissions on Army and Navy assigned frequencies, an emergency v-h-f transmitting channel has been provided on 140.58 Mc. The pilot desiring GCA service contacts the CAA airport traffic-control tower. The GCA voice transmissions are then made on the regular assigned station transmitting frequencies. For aircraft not equipped to receive either h.f or v.h.f, the instructions may be relayed on CAA facilities in the 200- to 400-kc band.

12. Direction Finders. Radio direction-finding facilities (DF) represent auxiliary aids to civil aviation available in two forms: the direction finder may be on the aircraft or it may be on the ground. For requisite accuracy with simple antenna equipment aboard the aircraft, direct space-wave reception is required; accordingly, low radio frequencies or very high radio frequencies must be employed. Since ground DF installations may have receiving antennas of any required degree of complexity, there are no restrictions as to frequency bands. High frequencies in the range 2 to 30 Mc may be utilized with sky-wave distance ranges of hundreds, or even thousands, of miles. Such distance ranges are particularly useful for transoceanic navigation. However, for overland operation, expediency has indicated the use of the direct space wave with corresponding ranges of the order of 100 miles.

Air-borne DF is utilized for homing purposes and for cross-bearing fixes. A four-band set, to cover the frequency range 100 to 1,759 kc, provides automatic bearing indication of the direction of arrival of r-f energy and simultaneous reception of intelligence. Such a unit may be utilized on any of the CAA 200- to 400-kc facilities with range depending upon the power of the transmitting station, with the exception that the loop ranges (RL, MRL, ML) are not suitable for direction-finder operations.

Another important facility that can be utilized by aircraft pilots for purposes of direction finding and fix determination consists of regular transmissions from commercial broadcast stations. All such stations having a power rating of 100 watts or more are listed in the "Flight Information Manual," both by operating frequency and by geographical position. Satisfactory use of broadcast-station transmissions as navigational aids is dependent upon a proper understanding of the properties and peculiarities of radio direction finders, inasmuch as reflected sky waves often produce serious interference with ground-wave signals.

Ground-station DF takes bearings on transmissions from the aircraft and, by triangulation between two or more stations, provides the aircraft with a position fix.

13. Organization of System Descriptions. Electronic avigation aids fall naturally into four categories which represent certain phases of flight. Equipment descriptions will accordingly be presented under the following functional classification: Part 1, The Equipment of the En-route Long-distance Zone. Part 2, The Equipment of the En-route Short-distance Zone. Part 3, The Equipment of the Approach and Landing Zone. Part 4, The Equipment of the Airport Zone (Surface Detection).

Very large expenditures have already been made by governments and by the aviation industry in establishing extensive communication systems, flight-path beacons, landing aids, and schemes for traffic control. Responsible agencies must consider these present facilities from the point of view of possible continued utilization and expansion, rather than from abandonment in favor of newer systems. This fact has been given wide recognition in the long-term planning which is being conducted by the Special Radio Technical Division of the International Civil Aviation Organization (ICAO). This division, on which representation is world-wide, has made an extensive study of civil air-navigation requirements along international air routes and has prepared specific recommendations covering the evolution of a broad program of expansion and development. The findings of its various committees represent the consensus of authorities on aircraft navigation and serve as a background for much of the material presented here.

PART 1

THE EQUIPMENT OF THE EN-ROUTE LONG-DISTANCE ZONE

The en-route long-distance zone has been defined[1]* as that portion of the airspace in which aircraft are primarily served by radio aids spaced at intervals of 200 miles or more, exclusive of the en-route short-distance, approach, and airport zones. A promi-

* Numbered references appear at the end of this chapter.

nent example of an en-route long-distance zone is a transoceanic area where the installation and maintenance of navigation facilities at short intervals would be impractical. Long-distance zones also include many land areas throughout the world where it is uneconomical to locate navigational aids at intervals less than 200 miles and indeed such installations may not be justified where traffic densities are low.

The requirements of long-distance navigation aids are not limited to directing the aircraft to an intended destination. For optimum efficiency, the system must be capable of directing the aircraft along minimum flight paths[2] so as to conserve fuel and time in flight. This indicates not only the ability to define a great-circle route but flexibility to deviate from this planned route so as to take advantage of pressure systems and wind currents aloft as may be reported by weather forecasts and observations.

In most cases, the navigation system itself must make possible the determination of the pressure (wind direction and velocity) pattern. This determination is normally based on two or three successive fixes and is therefore dependent on the relative fix accuracy rather than on the absolute fix accuracy. Therefore, it is important that the navigational system should give good relative accuracy between fixes (to determine ground speed and direction) as well as absolute geographical fix accuracy.

In establishing requirements for a long-distance system of air navigation the Special Communications Technical Division of the International Civil Aviation Organization (ICAO)[3] stated that the system shall

1. Make continuously available an indication of the aircraft's geographical position by a recognized method of fixing relative to the ground
2. Provide to the pilot a continuous visual indication which will enable him to follow any operationally desirable track
3. Be capable of providing for either automatic or manual flight
4. Be capable of satisfactory operation despite atmospheric or propagational disturbances and the effects of terrain
5. Be capable of being integrated into an over-all system providing automatic take-off, en-route flight, position reporting, air-traffic control, and landing
6. Provide coverage with visual or aural indications to a distance of at least 1,500 nautical miles over water and 750 nautical miles over land
7. Have an order of accuracy such that position-fixing error will not exceed 10 nautical miles at distances greater than 1,000 nautical miles, or 1 per cent of the distance between 1,000 nautical miles and 500 nautical miles, or 5 nautical miles at distances less than 500 nautical miles

In 1954, the ICAO Communications Division at its fifth session[4] recommended that the operational objectives listed above be reviewed, particularly in view of the probable performance of the systems then under development. In the material that follows, all the systems in use throughout the world, together with some of the newer developments, are described.

14. Air-borne Direction Finders and Radiophares. It is common practice in the United States to use the l-f four-course radio-range station as a source of radiation on which bearings can be taken with aircraft direction finders, but in other parts of the world special stations are often erected for this purpose. These stations operate on frequencies from 200 to 1,600 kc.

Nondirectional ground stations used as a source of radio transmissions on which bearings may be taken are referred to as *radiophares* and are probably the simplest form of navigational aid. Stations of this character form the backbone of navigational systems in South America and in various parts of the globe. In the United States, plans have been discussed for the installation of high-powered nondirectional stations as auxiliary aids when the four-course low-frequency radio ranges are decommissioned.

15. Loop Receiving Antenna. The loop antenna is the device that forms the basis of all low-frequency aircraft direction finders. Reference to Fig. 2 indicates that the receiving loop antenna is a winding composed of any number of turns of wire. Since an incident radio wave contains a magnetic-field component, the loop can be considered as a secondary of a transformer subjected to a magnetic flux of varying

intensity. The magnetic field in a normally polarized wave is at right angles to the direction of propagation. If the wave is traveling parallel to the plane of the loop ($\theta = 0°$) it will cut first one side and then the other and produce the greatest phase difference in the voltages induced. If, however, the plane of the loop is at right angles to the direction of wave travel ($\theta = 90°$) the magnetic field will cut both sides of the loop simultaneously and generate the maximum voltage.
Fig. 2. Relation of loop antenna to direction of wave propagation.

If the voltage is plotted as a function of θ, the resulting curve will be the familiar figure-of-eight pattern. That is, as a loop receiving antenna is rotated about its vertical axis, there will be two positions for which the output is 0 and two for which it is maximum.

It can be shown that, whether the induced voltage is considered a phenomenon caused by the electric or magnetic field, the results are the same. In essence, detecting the voltage induced in the loop, and determining its variation with loop orientation, forms the heart of a direction-finding system.

In air-borne radio-compass work, a shielded loop is used to improve the electrical properties and to serve as an ideal mechanical construction capable of withstanding aircraft service. The metallic cover forming the shield has a break at one point and is connected to ground. The circulating currents induced in the shield are negligible for all practical purposes. The magnetic field penetrates the shield and acts upon the conductors within to induce a voltage as discussed above. Hence, the figure-of-eight pattern will continue to prevail.

16. Simple Direction Finder. In its simplest form, the aircraft direction finder consists of a loop antenna (usually of the shielded type), a loop bearing indicator, a radio receiver, a receiver tuning unit, and a loop rotating gearbox. In operation the receiver is tuned to any desired station and the loop is rotated until the signal disappears. The bearing obtained is then compared with a magnetic compass so that its value as a function of north may be known. Two such bearings obtained from suitably located stations determine the location of the aircraft and constitute a "fix."

The bearing is obtained from the null rather than the maximum of the signal since the null has greater sensitivity with respect to azimuth and provides better accuracy.

17. The Radio Compass. The basic elements of the radio compass were first described by G. G. Kruesi[5] in a patent disclosure of November, 1930. In essence, the system depends upon the difference of the phase of induced voltages in a loop antenna as opposed to an open antenna. Because of its electrical characteristics, a loop antenna provides a voltage 90 deg out of phase with the voltage induced in a nearby open antenna. When combined in the proper proportion this receiving system provides a cardioid pattern and thereby resolves the bidirectional ambiguity.

In practice, the loop is mounted so that its plane is at right angles to the major axis of the aircraft. Both the loop and the vertical antenna are connected to a special radio receiver. The elements of operation are indicated in Fig. 3. If the loop is connected to the receiver by means of a reversing switch, the field pattern of the antenna system (the cardioid) can be made to reverse. If a meter having two opposing windings is connected to the rectified output of the radio receiver, and the connections to this meter are changed as the loop reversing switch is changed, the meter will move to the right or left depending upon the position of the transmitting station. If the nose or tail of the aircraft is pointing to the radio station the indicator will read zero. If the reversing switch is moved with sufficient rapidity, it will deflect only an amount proportional to the difference between the receiver outputs for the two loop connections. In actual equipments the reversing mechanism is normally done by electronic means. In practice, the sensitivity of this system is adjusted so that a deviation of 5 deg from directly ahead produces full-scale deflection of the instrument.

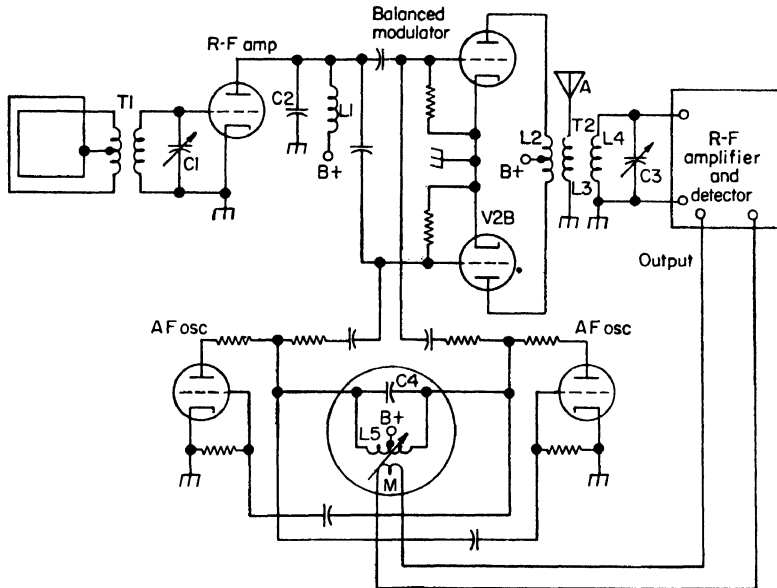
Practical equipments use a system of modulating the r-f energy as shown in Fig. 4. With this circuit the deflection of the indicating meter is determined by both the amplitude and phase of the audio tone. For a station dead ahead the audio tone output is zero. This tone may also be connected to headphones and thereby provide the
Fig. 3. Principle of the right-left compass.


Fig. 4. Elements of the right-left compass.

pilot with an aural output which is zero only when the aircraft is pointing directly at the station.

18. Automatic Direction Finder. The right-left radio compass was never widely adopted by commercial-air-transport operators or by military operators. Its major disadvantage is that, in the presence of a cross wind, the aircraft traverses a path much longer than the shortest path between the starting point and destination. This homing procedure can be minimized by continually referring to a magnetic compass, but this procedure detracts from the usefulness of the radio compass. The automatic

direction finder was suggested by F. L. Moseley[6] on Oct. 22, 1937. Several devices of this type have been developed and have found wide acceptance by the air lines. The principle of operation is shown in Fig. 5. In essence, it consists of a sensing device such as a contact on either side of the moving needle. As the needle touches one of the contacts, by virtue of the fact that the radio station is to one side or the other, a motor is set in motion. This motor rotates the loop which, unlike that of the right-left radio compass, is not fixed. Hence, the main difference is the movement of the loop rather than the reorientation of the entire aircraft. When the loop is rotated until its plane is at right angles to the direction of propagation the needle returns to zero and the motor stops. By displaying the position of the loop, the bearing between the heading of the aircraft and the radio station is indicated. By two or more such readings, the aircraft position may be fixed.

FIG. 5. Principle of the automatic direction finder.

Actually the circuit of Fig. 5 merely serves to illustrate the principle. Electronic circuits are substituted for the contact mechanism described above.

19. Radiophares. The ground station used with aircraft direction finders is termed a radiophare. A radiophare must produce sufficient field strength to permit the satisfactory operation of the air-borne direction finder under the conditions of atmospheric noise normally encountered. With narrow filters provided in automatic direction finders, good operation can be obtained with a signal-to-average-atmospheric-noise ratio of the order of 1:1, provided that the field strength is not less than 20 μv per m. During daytime, the noise will normally be less than 20 μv per m. Hence, the limiting condition is the inherent noise of the receiver. However, beginning just before sunset, the atmospheric noise level rises sharply and reaches a value of approximately 100 μv per m. Therefore, it is necessary during the night hours for the radiophare to produce a field strength of at least 100 μv per m to ensure satisfactory operation.

As an indication of the range capability of radiophares the following approximate figures are given: A 1-kw transmitter operating at 300 kc will normally produce 100 μv per m over mountainous terrain to a distance of 100 miles, over fertile soil to more than 500 miles, and over sea water to greater than 1,000 miles.

20. Four-course Low-frequency Radio Range and Markers. The four-course l-f radio range has been the primary device for furnishing guidance to aircraft in the United States since 1929. These stations operate in the band from 200 to 415 kc, where only approximately 65 channels are available. For this reason,[7] in the United States it was necessary to reduce power so that mutual interference would not result. Because of this power reduction, the l-f radio range is sometimes considered to be an en-route short-distance aid. However, with sufficient power it is capable of giving guidance over long distances.[8]

Because the four-course radio range is essentially a homing device, some alternate means must be employed to obtain a fix while flying the facility. With ranges alone, a fix can be obtained only over the station (termed the *cone of silence*) or at intersections of ranges. As the airway system expanded, fixes became necessary at other than these limited points. Markers were developed for this purpose which radiate a cone of signal rather than one of silence. These markers can be used to mark various points

along the courses of the l-f range. While it is true that markers have other purposes than described above, they are normally closely associated with the operation of a four-course radio range and are therefore described in this section.

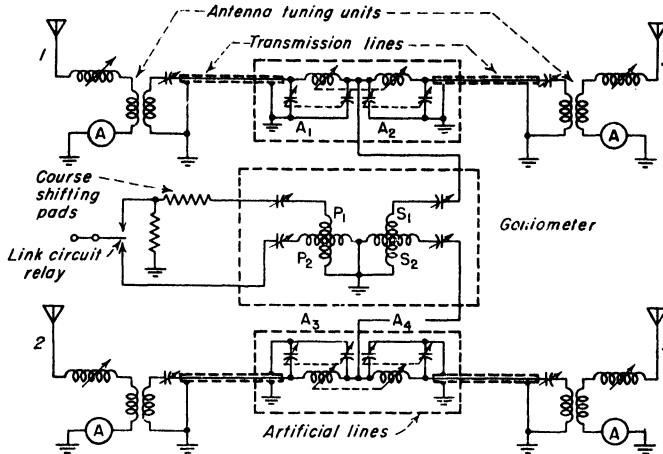
21. Radio Range. Early radio ranges utilized two loop antennas spaced at right angles to each other. The United States ranges employed polygonal loops 50 ft high,


FIG. 6. Range-beacon antenna-coupling system.

200 ft across the base, and 30 ft on the extreme sides. Each loop produced a directive pattern referred to the plane of the loop. Although the two patterns were identical, they were displaced in space by 90 deg because of the loop orientations. Therefore, at 45 deg to each loop, and only at this point, signals received from both loops would be equal. The early equipment made use of this principle by utilizing a modulated transmitter which was alternately connected first to one loop and then to the other. If the dwell time were different, for example, 3 sec on the first loop and 1 sec on the second loop, a Morse code resembling A or N would be audibly received to either side of the course. For the 45-deg position the switching of the transmitter from loop to loop would not be observed and a continuous tone would be heard.

To minimize night effect, the loop antenna was replaced by vertical steel towers fed by buried transmission lines. The complete antenna system comprises five self-supporting base-insulated steel towers approximately 130 ft high, four of which are placed at the corners of a square 300 to 500 ft on a side, and the fifth at the center of the square. The essential portions of the antenna system are shown in Fig. 6. The principle of operation of the radio-range beacon is evident from Fig. 7. The four outside
FIG. 7. (a) Space radiation pattern of simultaneous l-f directional range-beacon and voice broadcast station. (b) Range-beacon signals produced.

antennas form overlapping figures of eight when operated in pairs of two. The intensities of the side-band emissions (formed by the two directional-antenna systems), and hence the intensities of the detected signal produced by beating the side-band emissions with the nondirectional carrier, are equal along the lines which bisect the angles between the two antenna systems. An aircraft may follow these bisectors if means are provided for distinguishing the radiations from the two directional antennas. For this purpose, an automatic keying relay keys the radio power to one of the directional antennas in accordance with the Morse character N and the power to the second directional antenna in accordance with the Morse character A. The coded signals are sent out in groups and are interlocked so that along any of the four courses they form a continuous signal interrupted every 35 sec by the station-identification signal. The "on-course" signals are obtained along zones 2 to 3 deg wide. Off the course, the monotone signal breaks up into the component A and N signals, one or the other being of greater intensity depending upon the side "off course."

The coupling system between the transmitter and the directional antennas incorporates a keying relay, a goniometer, a course-shifting pad, artificial line sections, concentric transmission lines to the tower antennas, and antenna-coupling tuning equipment. The relay is energized by a motor-driven keying device so as to key the r-f power to the primary windings P_1 and P_2 of the goniometer in accordance with the required N-A sequence indicated in the foregoing description. The goniometer offers a convenient method of orienting the beacon space pattern, and the course-shifting pads and artificial line sections are used for shifting the range-beacon courses from their normal 90-deg relationship in order that they may be aligned with the required airways. This course shifting permits the angle to be placed between 60 and 120 deg rather than being fixed at the normal 90-deg position. In this way, the legs of the range can be arranged so as to bear on airways leading from or to a city. Precautions, in the form of special automatic phase and amplitude control of the antenna currents, are provided to ensure stability of the space pattern.

The transmitter employs two independent r-f channels controlled by two matched quartz crystals spaced 1,020 cps apart. Continuity of service is ensured by means of complete standby equipment provided with an automatic transfer relay. In the absence of speech modulation, the setup forms a single-side-band system having 1,020-cycle modulation. The carrier is radiated nondirectionally by the center tower, whereas the side band has the characteristic radiation of the radio range beacon. When speech modulation is applied, the central tower radiates these side bands nondirectionally. Therefore, the system provides simultaneous weather broadcast and directional guidance. Appropriate filters are used both in the ground transmission and in the air-borne receiver to eliminate interference between the speech frequencies and the 1,020-cycle beacon signals.

22. Marker Beacons. To correct the difficulties associated with the identification of the cone of silence over a range station, there was installed and commissioned on Jan. 1, 1939, on the airways of the United States a different type of terminal indication known as the *Z marker*. The marker operated at 75 Mc and consisted of a transmitter on the ground which actuated a separate receiver on the aircraft. Primarily the indication in the cockpit consists of a light that illuminates as the aircraft passes over the transmitting array, but an aural indication in the form of a continuous 3,000-cycle tone is simultaneously heard. Dual transmitting equipments are employed and have a nominal output of 5 watts. Automatic transfer is arranged in the event of a failure of one transmitter.

The antenna array consists of four horizontal half-wave elements connected so that one pair differs 90 deg in phase from the other pair. In this manner essentially circular polarization results. The array is mounted a quarter wavelength above a wire screen that serves to project energy upward.

The demand for fixes while flying the radio range, at points other than the terminal, was first met by use of intersections produced by two range systems. Special l-f radio ranges were employed for a time solely for marking purposes, but the lack of sufficient l-f channels was a big disadvantage. The problem of unlimited fixing facilities was met by the use of a 75-Mc marker not unlike the Z marker previously described except

that this so-called *fan marker* was placed on an airway instead of at the radio-range position.

Because an aircraft might be to the right or left of the "on course" of the radio range, it is necessary that the marker for these range legs have some breadth extending at right angles to the major dimension of the range course. At a 1,000-ft altitude, the radiation pattern extends 2 to 4 miles along the range course and approximately 12 miles across the course. In order that the fan indication might be received over the required area without the necessity for changing receiver sensitivity, it was essential that the power of its transmitter be greater than that of the Z marker. Consequently, the fan-marker transmitter is rated at 100 watts.

The antenna forming the fan pattern consists of four half-wave elements all located coplanar and with their longest dimensions in line. Each element is excited in phase with the element next to it. The entire array is located a quarter wavelength above a galvanized-iron screen.

In addition to furnishing aircraft with a check as to progress along airways, the fan marker is also used to mark the junction of two radio-range courses, to designate hold-over points along an airport approach, or to mark an obstruction.

A low-power version of the fan marker, with a nominal power output of 5 watts or less, is used for special purposes such as let-down along a radio-range course or localizer course.

23. Consol (Sonne). Consol represents one of the more important l-f systems of navigation in the long-distance zone. The system was developed by Germany early in the Second World War and was used extensively under the name of Sonne. The English radio observers deduced the significance of these radiations and made use of the signals for navigating aircraft of their own forces. For security reasons, the system was renamed Consol. The greatest advantage of the Consol system is that it is capable of giving accurate bearings over long distances and yet the only air-borne equipment required is a standard communications-type receiver. Its greatest disadvantage is that a comparatively long time (in excess of 30 sec) is required to obtain a reading of bearing and at least double that time is required to obtain a fix by establishing bearings to two stations. The system does not produce a visual presentation of the bearing data and cannot readily be adopted for automatic guidance of aircraft.

As late as 1954, Consol was one of the systems considered for international standardization by the ICAO.[9] However, it was not standardized, but was approved for long-range use together with loran and radiophares.

The basic antenna system comprises three radiators, as shown in Fig. 8, spaced 3λ apart. The antenna currents in the outside radiators are one-fourth of the current in the central radiator and 90 deg leading and lagging in phase, respectively. This antenna combination produces the pattern shown in Fig. 9.

In the initial system (called Elektra) the phases of the currents in the outside radiators were successively reversed according to a dot-dash time cycle so that one of the overlapping patterns was characterized by a series of dots and the other by a series of dashes. At the intersections, the dots and dashes merged into a continuous signal and thereby resembled the operation of the l-f four-course radio range.

The system later evolved into Sonne, in which the phases of the currents of the outside radiators were shifted from their respective 90 deg leading and lagging values continuously in opposite directions during a 1-min interval at a rate of 3 deg per sec. Simultaneously, the currents in the radiators were reversed according to the dot-dash time cycle. There is thus produced a slow rotation of the equisignal lines so that, at the end of the 1-min interval, the dot-and-dash patterns have become completely interchanged and each equisignal line then occupies the position of the one adjacent to it at the beginning of the interval.

In the Consol system, Fig. 9 indicates that coverage is provided for only approximately 240 deg of the total 360 deg. The Consol lobes each occupy a sector of about 10 deg. Every other lobe transmits a different Morse character (E or T), the E signal being transmitted in one-third the time of the T signal. Between the lobes, the interlocking signals produce a continuous tone. With the large number of similar lobes that are present, it is necessary to determine position with an accuracy of at least ±20 deg by using an air-borne direction finder before a more accurate position can be determined. The accurate position
FIG. 8. Antenna spacing and phasing for Consol beacons.

is determined by counting the relative number of E and T characters that precede and follow the "on-course" signal.

The usual cycle of operation of a Consol station is about as follows:

1. Omnidirectional transmission with identifying station letters for 28 sec.
2. Break for 1.5 sec.
3. Transmission of 30 each of the E and T characters while the lobes rotate for 30 sec.
4. Break for 1.5 sec.

Specially prepared charts are available to convert E or T total counts into bearing for each station.

The transmitting equipment used for generating the Consol signals is essentially a standard nonmodulated c-w transmitter with crystal control operating in the 200- to 300-kc band. The output of the transmitter is connected by a transmission line to the tuning units of the central radiator and also to the Consol signal-generating unit. The signal-generating unit in turn is connected to the two outer radiators. Maximum output of the usual transmitter is about 2 kw. However, some equipments having a power output of up to 50 kw have been planned. A presentation of the apparatus arrangement is shown in Fig. 10.

With the use of simple narrow-band airborne receivers having sensitivities of the order of 1 μv per m, the Consol system provides services to approximately 400 miles over poor terrain, 800 miles over good terrain, and 1,000 miles over the sea during daytime. At night, sky-wave propagation becomes a factor and ranges in excess of 1,000 miles can be realized for all types of terrain. Under normal conditions, and excluding propagation anomalies that occasionally take place, bearing accuracies within 1 to 2 deg are possible.

FIG. 9. Field pattern of Consol station.

Many descriptions of improved forms of Consol have appeared in technical publications. One such system, developed in the United States, was installed largely to

obtain propagational data but has not been employed for use in routine air operations. It consists of a twin two-tower system with one tower doing duty in both systems. All three towers are in line. Normally only the dual-purpose tower and the outermost radiators are energized. The spacing between these towers is three wavelengths and the pattern produced in space is identical to that described. At intervals, however, the intermediate tower (located one wavelength from the dual-purpose radiator) is energized in place of the outermost radiator. With the closer-spaced towers, a four-lobed pattern is produced that may be employed to resolve ambiguity without the use of a direction finder.

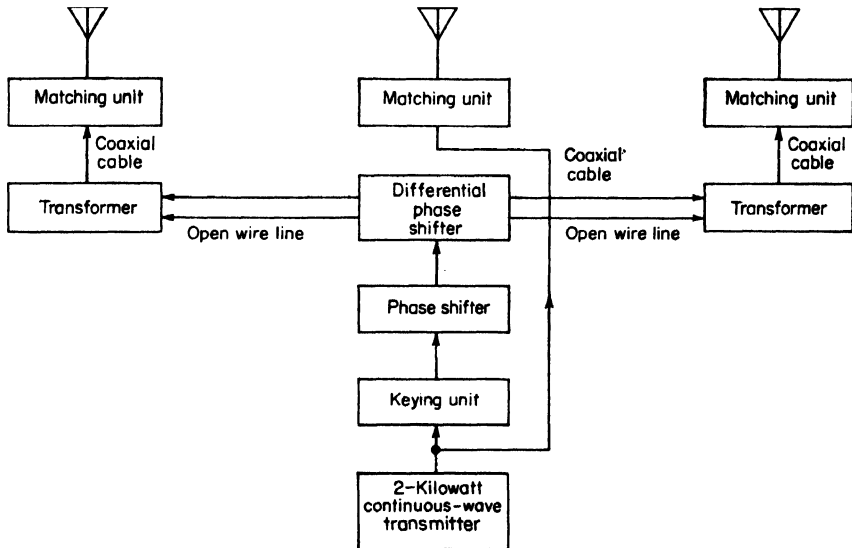
The United States system also employs several other novel features. A goniometer is connected at the output of an oscillator instead of to the output of the transmitter. Transmission lines connect the oscillator to 10-kw power amplifiers located at the base of each of the three radiators. In this manner the problem of handling high powers


FIG. 10. Consol transmission system.

with the goniometer is avoided. By use of this technique, error produced by transmission-line radiation is also avoided and there are no losses to affect the system efficiency.

24. Some Low-frequency Developments. The existing long-distance navigation aids described previously do not fully meet the requirements of ICAO. Accordingly, a number of devices are in various stages of development which their sponsors hope will provide better solutions and be considered for adoption by ICAO. This section describes the most prominent of these developments which have progressed to the testing stage.

In connection with these developments, studies[10,11] have been made to determine what frequencies are best suited for the operation of long-distance ground-based aids. The fundamental requirement is that reliable and undistorted signals must always be present, regardless of propagation conditions, to a distance of at least 1,500 miles from the ground station. Frequencies above 30 Mc are unsuitable because of typical line-of-sight limitations. The daytime attenuation of frequencies between 400 and 1,500 kc is also considered unsuitable because of the excessive power required. Frequencies between 1,500 and 30,000 kc are attractive because of high-efficiency antenna structures, low power, and low static levels. However, these frequencies are charac-

terized by skips wherein the signal is not efficiently reflected back to earth at certain points, and simultaneous transmission[12,13] on several frequencies would be required. Also, these frequencies have been found to be susceptible to rapid fading.[14,15] Studies have concluded, from data accumulated over a period of years, that frequencies between 10 and 150 kc offer the most reliable service, except for certain climatic and seasonal variations.[16] Taking into account economic factors, power requirements, and noise levels, a generally accepted optimum compromise is at frequencies of about 100 kc.

25. CAA Low-frequency Omnidirectional Range. Following the successful development of the v-h-f omnidirectional range, CAA began the development[17] of an l-f device of a similar character. The device was intended for use in the 200- to 400-kc band, when that band was made available by the discontinuance of the l-f four-course range. Unlike the four-course range, the omnidirectional range could supply navigational data at all azimuths, rather than being restricted to four specific courses. The intent was to supply transoceanic and perhaps some national long-distance navigational service.

The principle of operation involves two radiated signals. One of these, transmitted omnidirectionally and having a characteristic modulation, is known as the reference signal. The second signal employs a figure-of-eight field pattern which is not modulated. The figure-of-eight pattern is, however, continuously rotated at a rate of 1,800 rpm, thereby producing a 30-cps modulation at the observing point. The modulation of the first omnidirectional transmission comprises a reference signal against which the phase of the variable or rotating signal can be compared. If the equipment is adjusted so that the voltage of the modulating frequency of the reference signal is a maximum as the figure-of-eight maximum is passing through north, the phase between the reference signal and the variable signal will be directly proportional to the deviation from north.

To avoid the necessity for two carriers, one radio frequency is used and modulated by a 210-cps subcarrier. Accordingly, at a spacing of 210 cps from the carrier, a separate sideband signal appears that can be separated in the radio receiver. The subcarrier is in turn frequency-modulated by a 30-cps signal which, when properly demodulated, provides the reference signal.

The variable-phase field is produced by an unmodulated carrier fed to the rotor coil of an inductive-type goniometer. The two stators of the goniometer (disposed at right angles) feed two pairs of diagonally disposed vertical towers identical to those described for the simultaneous radio range. When the rotor is rotated at 900 rpm, and the two pairs of towers are driven 90 deg out of phase, the resultant radiation pattern is a figure of eight rotating at a 30-cps rate. Since it is imperative that the phase of the reference and the variable signal be in absolute synchronism, the reference-signal generator is driven by the same motor that rotates the goniometer. The reference generator takes the form of a seven-tooth tone wheel which normally produces a frequency of 210 cps. By varying the angular spacing of the teeth, the 210 cps is given a frequency modulation of 30 cps.

The transmitter used with this development was derived from the transmitter of the four-course simultaneous radio range, with both channels operated on the same frequency. The tuning of the antenna array involves the following phase adjustments:

1. The currents in the diagonally opposite towers of a pair must be related by 180 deg and must be equal in amplitude.
2. The phase relation of the currents in the tower pairs must be zero or 180 deg.
3. The phase of the current in the central tower must be 90 deg with respect to the currents in the outer towers.

When the radiated signals are properly demodulated and processed, the air-borne receiving equipment yields two 30-cycle components whose phase difference indicates the bearing from north. A bearing selector is used to provide a means for indicating the bearing. This comprises a phase shifter which changes the phase of the reference signal as received, until it has the same phase as the variable signal. To make this measurement sensitive, a zero-phase detector is used consisting of a phase-discrimination circuit and a zero-center d-c meter. By rotating the bearing selector so that the meter indicates zero, the bearing may be read. Conversely, a desired homing track may be set into the bearing selector and the aircraft flown so that the indicator remains centered.

The system was intended to provide a useful range of 600 miles or greater overland with an accuracy of within ± 3 deg. Tests of the quadrantal errors made at a distance of 6 miles

from the station showed them to be of the order of ±2 deg. Recordings made at a distance of up to 570 miles failed to disclose selective fading between the two components of the signal.

26. Post Office Position Indicator (POPI). Early in 1941, the British Post Office was asked by the Admirality to consider the development of a precision navigational aid for shipboard use under conditions of low visibility. The result of this work was a c-w phase-comparison system known as POPI.[18]
FIG. 11. Lines of constant phase difference and radiation pattern in horizontal plane for radiators spaced $\lambda/2$ apart and in phase synchronism.

System operation is based on the hyperbolic principle which is illustrated in Fig. 11. If two radiators A and B, spaced $\lambda/2$ apart, are excited in phase from the same transmitter the phase of the signals will remain zero along the perpendicular bisector of the array. Conversely, along the line of the array, the phase difference will be 180 deg. Between these two positions, all phases between 0 and 180 deg exist, and the loci of all equiphase points form a family of hyperbolas. Accordingly, by knowing the phase difference and wavelength, it would be possible to determine the hyperbolic line of position on which the observer is located with respect to the transmitting station.

Since the hyperbolic lines are not equally spaced for a two-antenna system, it is apparent that accurate bearing indications cannot be obtained at all azimuths. To correct this condition, the POPI system utilizes radiation from three antennas arranged at the corners of an equilateral triangle. The sequential transmission from pairs of the three-antenna system then supplies nearly equal accuracy at all azimuths. In addition, by making readings on a second pair, the ambiguity that is present can be eliminated.

Since it is not practical to measure the phase difference between two transmissions on the

same frequency, POPI resolves the problem by alternately keying each radiator with dashes, followed by a pause. The pause serves to identify the dashes; that is, the first dash after the pause is known to radiate from A, the second from B, etc. The system then transmits a second carrier frequency, at a constant frequency difference from the first, and these two frequencies when beat in the receiver form the desired audio frequency for measurement of phase difference. The carrier frequencies differ by a value of 83⅓ cps maintained constant by a monitor and control circuit referenced to a tuning fork.

In the receiving system, the 83⅓-cps tone provides a means for separating the transmitted dashes. The tone drives a synchronous motor which, in turn, commutates and distributes the outputs of the receiver to the phase-measuring circuits. Although this provides the proper speed of rotation, a proper starting phase is also necessary and is accomplished by reference to the blank position in the sending sequence.

To determine bearing, a means is necessary for reading the phase difference between the radiated signals although they are not present simultaneously. In the transmission, this is provided for by a commutator rotating at 5⅚ rpm driven from the 83⅓-cps frequency. The commutator then keys the oscillator frequency to the amplifiers located at the various radiators. The result of this modulation is a wave consisting of a frequency of 83⅓ cps with side bands of 5⅚ cps. By using a narrow band-pass filter to separate out the low-frequency side bands, the carrier frequency of 83⅓ cps is restored in the air-borne equipment. If the length of each dash is made an integral number of half cycles of 83⅓ cps, the phase of this frequency will be the same as that of the original r-f carrier. With the transmissions separated by the commutator, these signals may be connected to a standard phase meter to indicate the phase difference directly, or a null meter similar to that described for the CAA omnirange.

The only data available to date are a series of measurements made relatively close to the transmitting stations. These measurements taken at all azimuths show most errors to be under 1 deg but some, because of site errors, were as much as 15 deg.

27. Navaglobe-Navarho. These are the names applied to a long-distance l-f aid developed by the Federal Telecommunications Laboratories.[19,20] Navaglobe applies to the system when bearing alone is furnished, but if an additional translator is added to the air-borne equipment it becomes a Navarho system which can supply both bearing and distance. Official recognition was given to this system by the fifth session of the Communications Division of ICAO, which met in 1954.[21] Although not adopted as a standard, it was listed as a system that should be developed further to qualify it as a candidate for the ultimate common-standard long-distance navigation system.
Fig. 12. Navaglobe field pattern. (*IT&T.*)

Navaglobe makes use of three antennas at the corners of an equilateral triangle with a spacing of approximately 0.4λ. Physically, its separation amounts to approximately 4,300 ft at the operating frequency of 100 kc. In its simplest form, the energy from a common transmitter is commutated to one pair of antennas at a time. The resulting space pattern for each pair of antennas resembles a figure of eight with an incomplete null. Three such space patterns result with their relative axis displaced from one another by 120 deg. These patterns are shown in Fig. 12.

Except for the keying necessary to commutate the power to the different antenna pairs, the transmission is essentially c-w. The keying cycle is fundamentally 1 sec long and is repeated continuously under control of an extremely stable crystal oscillator. The cycle is illustrated in Fig. 13. During each 1-sec cycle there are four subintervals. During three of these subintervals, which follow in close succession, the three different combinations of antenna pairs are energized. In the fourth interval, one antenna is excited with an r-f energy differing by about 200 cps from that of the normal frequency which simultaneously energizes a second antenna. This transmission is omnidirectional and serves two purposes. The displaced carrier frequency serves to synchronize a commutator in the receiving equipment which makes possible the identification of the successive signals. In addition, the beat between the two carriers furnishes distance information. A total band width of

20 cps, centered at each of the two carrier frequencies, is all that is required to receive both bearing and distance information.

A second version of the Navaglobe-Navarho ground station makes use of a series of r-f amplifiers located at the base of each of the three towers. An accurate r-f source located in a central location drives the amplifiers. At this central location, keying and control of the amplitude and phase of the components of the signal are accomplished. Relative phase is maintained to 0.05 deg and amplitude to 0.1 db by measurement of the fields at the central location and control of the excitation to the amplifiers. Two amplifiers, operating in parallel, are used at the base of each tower to provide an input power of from 30 to 50 kw. When noise conditions are low, or in the event of failure of one amplifier, one unit may be disconnected.

Fig. 13. Navaglobe keying cycles. Pulses *A*, *B*, and *C* correspond to the three patterns shown in Fig. 12. The synchronizing pulse is transmitted omnidirectionally. (*IT&T.*)

The Navaglobe system (in contrast to POPI, which compares phase) determines bearing by comparing the amplitude of the three signals received during each cycle. The relative amplitudes vary with azimuth, as is evident from the space patterns shown in Fig. 12. The receiving equipment utilizes the principle that, if the three magnitudes were added vectorially with a 120-deg space relation, the angle of the resultant would be equal to twice the azimuth angle of the receiver from the transmitter. In practice, this is accomplished by commutating the signals, in a-c form, to the three coils of a sine resolver. The rotor coil, acting as a secondary in the selsyn, has voltages induced in it, the algebraic sum of which is zero when the angle of the coil is set to correspond to twice the azimuth of the receiver from the transmitter. This algebraic sum increases positively or negatively as the coil is shifted about the null point. For automatic direct reading, the resulting voltage may be used as an error signal to control a servomotor that rotates the coil to the null point. For manual operation, a bearing-selector knob attached to the selsyn may be rotated until the indicated-error signal is zero.

It can be noted from the symmetry of Fig. 12 that there are two positions of azimuth, 180 deg opposed, for which the ratio of the three field-strength amplitudes is the same. Hence the cycle repeats twice for a full orbit in azimuth, and the Navaglobe indicator utilizes an expanded scale wherein 360 deg of rotation corresponds to 180 deg of azimuth. The 180-deg resulting ambiguity is relatively easy to resolve in long-distance navigation.

To mitigate against errors produced by noise, the Navaglobe receiver utilizes a wattmeter-type square-law detector and further incorporates a broad-band clipping circuit at receiver input which is then narrowed to an acceptance band of only 20 cps at the output. The circuits also lend themselves readily to postdetector integration. Since each Navaglobe cycle requires 1 sec, a reading may be obtained by noting the position of the wattmeter detector after any number of cycles desired. The equipment is initially designed to provide a reading at the end of every 5 or 15 cycles at the operator's selection. Postdetector integration greatly smoothes and averages the resulting bearing and, under very high noise conditions, integration times of as long as 3 min may be desirable.

A Navaglobe station is capable of furnishing distance-measuring service without modification. In the air-borne equipment, the only modification required is the addition of a second translator unit connected to the output of the receiver. This translator consists of an extremely stable reference oscillator (having a stability of the order of one part in a billion), a count-down circuit, and a phase meter. As mentioned previously, the 200-cps beat, resulting from the simultaneous transmission of two carriers from the ground equipment, provides the basis for distance measurement. The wavelength at 200 cps is approximately 811 nautical miles. Thus, 1 deg of phase difference between the received 200-cps note and that of the local air-borne oscillator is equivalent to a distance of approximately 2.25 nautical miles. To determine distance, therefore, it is only necessary to measure the phase between the arriving note and that generated by the local oscillator. Assuming the phase-measuring system to be accurate to within 1 deg, it can be expected that the system will have an accuracy equivalent to ± 2.25 nautical miles plus any error associated with drift of the air-borne oscillator. The system requires manual adjustment of the phase meter to correspond to the known distance between the aircraft and the ground station at take-off, or over any known check point. At 811 nautical miles from the station, the indi-

cator will have completed a full cycle and will record zero distance. As the aircraft progresses further, it becomes necessary for the pilot to add 811 nautical miles to the reading of the meter. This procedure is followed for any subsequent 811 miles to the maximum range of the equipment. Since these distances are large, there is little possibility of confusion due to positional uncertainty, and therefore no ambiguity resolving circuitry is included.
Summer daytime tests of the Navaglobe system, radiating 6 kw of power, have indicated bearings up to 1,800 nautical miles over both land and sea. These same transmissions, during summer nighttime propagation, have given ranges of 2,000 nautical miles over land and 2,600 nautical miles over sea. Average bearings over a period of about 15 min were found to be within 0.5 deg of the true values. In the presence of severe thunderstorms, bearings within 4 deg of true value were obtained.
FIG. 14. Decca hyperbolic patterns.

28. Decca. This system, a development of the Decca Navigator Company of London, England, has been proposed for immediate use, but its development continues along the basic principles described here. Decca[22] is a hyperbolic system making use of c-w phase comparisons in much the same manner as POPI. POPI, however, uses a short base line between antennas so that the lines of position will be essentially linear with a maximum phase difference of 180 deg, whereas Decca uses extended base lines (approximately 70 miles) to increase accuracy. Although phase difference between a pair of stations would yield a line of position, Decca is planned as a system that produces a fix; and accordingly it utilizes three stations placed at the corners of an equilateral triangle. The Decca hyperbolic patterns are shown in Fig. 14. A master station is located at the center of the triangle and all measurements are based on phase difference between this central master station and the outer slave stations.

To resolve the problem of measuring the phase difference of two radiations at the same frequency, Decca uses a different frequency for each radiator but each frequency is some integral submultiple of a frequency common to all transmissions. As an example, one of the chains in use employs the following frequencies.

1. Master station is 14.16 × 6 = 85 kc.
2. Slave station *A* is 14.16 × 5 = 70.8 kc.
3. Slave station *B* is 14.16 × 8 = 113.3 kc.
4. Slave station *C* is 14.16 × 9 = 127.5 kc.

The exact values of the multiples are unimportant as long as they are capable of relating master and slave to a common frequency and are integral; for it is on the common frequency that the phase measurements are made.

Another problem that Decca has solved uniquely is that of the measurement of phase difference beyond ±180 deg. Decca employs a cumulative counter which can be set at any point at departure and which will thereafter indicate the total number of complete phase shifts.

The distance between Decca stations makes it necessary that the radiation at each point be generated by an independent transmitter. The radiated frequency is generated by receiving the master station and utilizing its frequency as the source of slave-station frequencies. This procedure assures synchronization between stations. It is further necessary that both master and slave maintain phase to within 1 deg. This is done by receiving the common harmonics of the slave and master stations and applying them to a phase discriminator which controls a reactor tube to correct the phase of the slave transmitter.

The Decca mobile receiver utilizes a phase-measuring system that is independent of the intensity of the voltages being measured. Furthermore, the phase meter has a free movement for a full 360-deg rotation and can therefore be geared to other dials that will add the total number of revolutions and record phase difference to any desired value. A fix is determined by the intersection of two lines of position established by two pairs of transmitters.

The ambiguity problem has been solved by a system of coarse-zone and fine-zone identification. The coarse-zone patterns are displayed on a meter having a sector-shaped pointer that indicates an area of 60 deg. On the face of this same meter are six pointers driven by a common shaft that is operated from the fine-zone identification. In operation, the lanes are identified as red, green, or purple lanes, and in an area that extends to 300 miles, there are 1,058 red lanes, or 1,350 green lanes, or 820 purple lanes. By an extra transmission of the master station, the number of these positions is reduced to about 45 and these are widely separated so that their ambiguity may be resolved by normal navigational means. Selecting the Decca lanes from within the 45 coarse zones is done by a second auxiliary transmission. The ambiguity resolving circuits in the mobile receiving equipment are put into effect by a change in frequency of the master station of 60 cps.

The accuracy figures quoted by Decca are shown in Table 2.

Table 2. Distance and Accuracy of Decca

Distance, miles	Accuracy, yd	
	Day	Night
50	10	20
100	20	50
200	40	200
300	100	500
500	200	
1,000	500	

29. Delrac and Dectra. These systems were recognized by the fifth session of the Communications Division of ICAO and were listed as developments to be encouraged. Both systems are the proposals of the Decca Navigator Company[23,24] and employ techniques closely associated with those which have already been described for the Decca system.

Delrac is a hyperbolic system operating in the 12- to 16-kc band, and may consist of one master and one slave station or as many as three masters each with one slave station, making a total of up to six stations. All stations transmit on the same frequency. Phase lock, however, is required only between a master and its slave. To avoid interference, the transmissions from the various stations are not present at the same time. In the aircraft receiver, a commutating system similar to that described for Navaglobe is used to connect the output of the receiver to crystal oscillators that store the phase of the master frequency. A measurement of the relative phase of a pair of these oscillators then produces the decometer deflections corresponding to the hyperbolic lines of position.

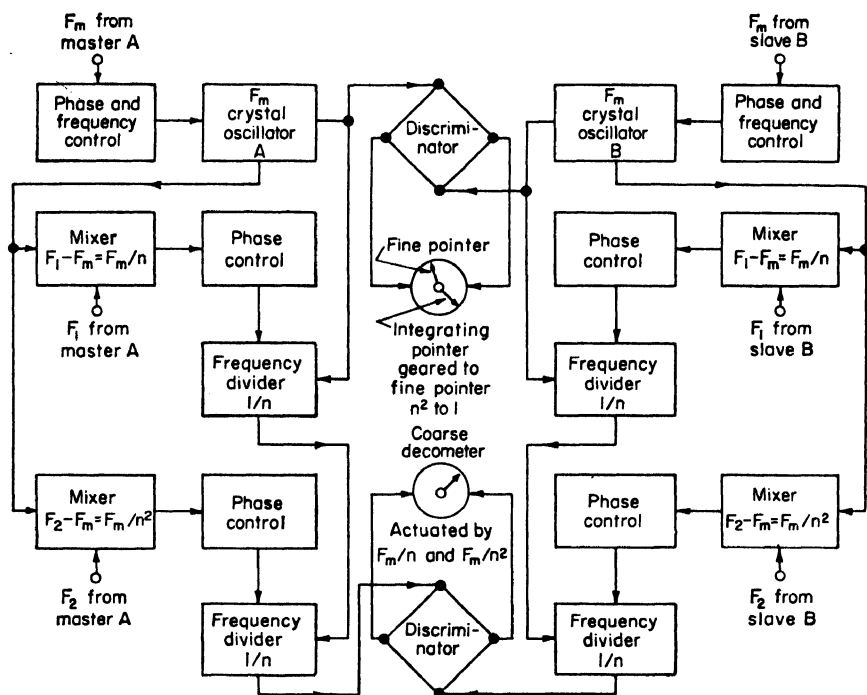
The ambiguity of the Delrac lines of position is resolved by additional transmissions from the master and slave stations. The operation of the equipment may best be understood by reference to Fig. 15. Let it be assumed that F_m equals 12 kc and n equals 3. Then $F_1 = F_m[1 + (1/n)] = 16$ kc and $F_2 = F_m[1 + (1/n^2)] = 13\frac{1}{3}$ kc. In the receiver, F_m from the A station controls the phase and frequency of oscillator A. Similarly, F_m from the B station controls oscillator B. The phases of oscillators A and B are compared in a Decca discriminator and displayed on a decometer. A phase difference of 360 deg corresponds to a distance of about 15.5 miles. Accordingly, although an accurate position indication is obtained, there will be an ambiguity every 15.5 miles. The ambiguity is resolved by extracting a beat note resulting from the mixing of the other frequency and by frequency division. This provides an ultimate frequency of $1\frac{1}{3}$ kc, for which a phase


FIG. 15. Delrac receiving system.

difference of 360 deg corresponds to a distance difference of 300 km. There is small likelihood of positional confusion of 300 km. However, if necessary, it is possible to incorporate additional circuits to make use of F_3 and compare frequencies of $1\frac{9}{27}$ kc.

Dectra. In contrast to Decca and Delrac, which are intended to provide essentially omnidirectional service, Dectra is designed to provide service only along a narrow predetermined route. For this purpose, a master and slave station are located about 80 miles apart on a line perpendicular to the route to be traveled. The master and its slave are equally distant from the route and one pair of stations is located at each end of the route. At any one time, track position is determined by the use of only one pair of stations, the second pair being used over the second half of the route.

In operation, the frequency of each master station is the same as its slave and each pair of stations transmits for periods of about 10 sec. The stations at opposite ends of the route, however, differ in frequency. For example, the master and slave at one end may transmit on 85.1 kc while the master and slave at the other end may be on 84.915 kc. Just as a station is about to terminate its transmission, its frequency is changed by 60 cps to cause

the other station of the pair to begin transmitting, and to cause certain switching functions to occur in the receiver.

In the receiving equipment, the phase of the transmitted frequency of the master station is stored by a crystal oscillator and is compared with the phase of the slave station. The equiphase lines of position are hyperbolic but, because the spacing between the master and slave station is small, most of the useful lines have small curvatures and may be regarded as radials originating at the bisector of the line connecting the master and slave stations.

Transmissions from stations at opposite ends of the route are employed to determine distance along the route. For this purpose, frequencies from the stations at opposite ends of the route are connected to a mixer where they beat to produce 185 cps. At the time of take-off, the range indicator is adjusted to read the known distance, and as the transmission from the distant master is received, the range indicator is automatically actuated through action of the distance circuitry.

30. Radux. Radux, a system of long-distance navigation suggested by Dr. J. A. Pierce,[25] employs very long base lines between stations. Radux transmissions are supplied by three or more transmitting stations located far apart in an arrangement similar to that employed by loran. The l-f transmitters are modulated at about 200 cps. The carrier frequencies need not be synchronized, but it is necessary that the modulation frequencies be carefully synchronized. The transmitters are keyed sequentially for a period of about 0.6 sec with a gap of 0.2 sec between transmissions. The sequence is stopped for about 0.8 sec before being repeated. The gap in transmission is used to identify the three transmissions.

Since the keying cycle requires in excess of 3 sec, the Radux receiver employs a very narrow keying-cycle filter that is expected to reject most of the noise. The output of the filter drives a commutator that connects the output of the receiver successively to three storing circuits. In one embodiment of the receiver, these storing circuits may be accurate 200-cycle tuning forks. A phase detector and servo are used to correct the phase and frequency of the forks so that they are in synchronism with the incoming signals. The outputs of three or more sets of tuning forks are then continuously compared in phase in circuits of the type that have already been described for the l-f omnidirectional range or Decca.

31. High-frequency Direction Finding from Ground Stations. Many types of ground-station direction finding have been devised for use in conjunction with air-borne transmitters operating in the l-f, m-f, h-f, v-h-f, or u-h-f bands. Two or more such DF installations, located at widely separated sites, will permit a fix on the location of an aircraft. Position determination can also be accomplished by means of a single DF operating in conjunction with range-finding equipment.

The useful range of an h-f or l-f DF depends upon many variable factors, including the frequency of transmission, the location and power of the transmitter, the time of day, and the season of the year. Although these factors do not apply to the same extent in v-h-f and u-h-f transmissions, these higher frequencies are limited to line-of-sight range. The accuracy of a DF is dependent upon such factors as atmospheric conditions, polarization, scattering, diversity, and site effects.

The h-f DF was not considered for standardization as an international long-distance aid by ICAO at its meeting in the fall of 1946, but it was recommended for use in several regions, notably the South Atlantic and Middle East. It is highly improbable that the device will receive recognition as an international standard long-distance aid; however, it serves a very useful purpose as an emergency ground aid to long-range navigation. In rescue work, it will probably continue to play an important part for many years to come.

32. Direction-finding Antennas. Antenna systems used with DF equipment are necessarily directional in their characteristics but may vary radically in their design. The simplest system makes use of a vertical-loop antenna supplemented by a nondirectional antenna, the combination producing a cardioid pattern. This system eliminates the 180-deg ambiguity which is present when a loop alone is used. Such an antenna can be made small enough so that it has found wide application on special-purpose portable equipment. Loop antennas are capable of good performance on

ground-wave signals but are adversely affected by reflected sky-wave signals, the latter inducing voltages in the horizontal sides of the loop and thus introducing bearing errors or instability. These polarization errors are greatly minimized by employing the Adcock antenna or the spaced-loop antenna.

33. The Adcock Antenna. In 1919, an English patent[26] was granted to Adcock for a DF antenna system having, as its main purpose, the elimination of polarization error. Fundamentally, the principle involved the use of elements sensitive only to the vertically polarized component of the radio wave. Various forms of this antenna system are shown in Fig. 16, where the antenna shown at *A* is the original or U-type form. The other forms shown are modifications by later inventors for the purpose of further reducing the polarization error. The basic theory of the Adcock array depends upon the figure-of-eight pattern which is formed when the spacing between two elements is small compared with a wavelength. If the spacing is greater than $\lambda/2$, a multilobed pattern is produced which will result in ambiguities.
Fig. 16. Common forms of Adcock antenna systems.

Practical Adcock arrays utilize two crossed Adcocks associated with an inductive-type mechanical goniometer, or its electrical counterpart, and form the equivalent of a rotatable single Adcock. This arrangement is shown in Fig. 17. The mechanical goniometer utilizes a rotary search coil which is coupled to the two stator windings crossed at right angles, with each fed by one Adcock. The resultant flux in the goniometer will be the vector sum of the flux produced by each field coil. Accordingly, if the search coil is rotated until the voltage induced is maximum, it will be in a position (with respect to the plane of the goniometer coils) corresponding to that of the plane of propagation of the radio waves with respect to the Adcock antennas. For greater sensitivity, the bearing is obtained by rotating the search coil until a null is received, and noting the position of the coil at this time.

The electronic goniometer may take a variety of forms. In one form, two balanced modulators supply a two-phase modulating voltage to the Adcock system. The two Adcock antennas feed a common receiver, but the signal voltages corresponding to the two antennas may be individually recovered in the receiver output by reference to the two phases of the special modulating or scanning signal. In a second form, the north-south antenna is fed to the receiver through a balanced modulator operating at one audio frequency, while the east-west antenna is fed through a second balanced modulator operating at a different audio frequency. The resulting two side bands are amplified equally, passed

through filters, and are used to represent the amplitude and phase of the voltages induced in the two Adcocks by the incoming wave. With either form, sense of the bearing may be introduced by proper combination with the output of a nondirectional antenna.

34. The Spaced-loop Antenna. Another means for minimizing the effects of abnormally polarized waves is the spaced-loop system devised independently by R. A. Weagant in the United States and C. S. Franklin in England, and later investigated and developed by T. L. Eckersley.[27] The principle of operation is illustrated in Fig. 18. The loop antennas are connected in phase opposition and the pair is then rotated about a vertical axis through point P to seek a null. Analysis of the system indicates that, regardless of the value of the incident and polarization angles, the spaced-loop output voltage goes through a null when the directions of propagation are contained in the planes of the loop antennas. This differs from the Adcock antenna in that the
FIG. 17. Goniometer for Adcock system. Outer coils go to antennas and bear a 90-deg relation to each other. Inner coil rotates.

spaced-loop DF makes no attempt to reject any component of the impinging wave. Measurements made by Eckersley concluded that the polarization error was only 0.3 deg. When the direction of propagation is normal to the plane of the loops, additional nulls are produced which are referred to as "loop nulls." Under these conditions, it is often necessary to provide a means for resolving the ambiguity.

35. Direction-finder Systems. All DF stations require a directional receiving antenna, a radio receiver, and a bearing indicator. To determine fixes, the control center is also required to coordinate the operation of a station network. Complexity of equipment may vary from lightweight portable units to large fixed installations, depending upon the nature of service and upon the requirements for elimination of polarization errors. The effectiveness of any DF system may be materially increased through proper instrumentation which gives simultaneous visual indication, through panoramic techniques, of all frequencies received. This assures that any desired signal will not be overlooked if slightly off frequency.

Ground-station DF can employ either aural or visual indications, or both. Aural indication of the bearing is obtained by rotating the antenna or goniometer until a

null point is reached, and has the advantage that bearings may often be taken under high noise conditions where visual means often fail. Visual indications may be presented in the form of a minimum reading on a meter or, more generally, as deflections on the screen of a cathode-ray tube graduated in degrees around its outer edge.

With cathode-ray displays, the goniometer must be rotated at high speed, mechanically or electronically, to obtain a stable pattern on the screen. Modern DF favors the use of electronic scanning with units of the antenna system remaining stationary. Cathode-ray indications may take a large variety of forms but are usually arranged to give a lobe or line of indication on the tube corresponding to the direction of arrival of the received wave. Typical indications are shown in Fig. 19. One such indicator
Fig. 18. *BD*, direction of incoming wave. *CO*, perpendicular from *O* to *C*. *AO*, difference in distance traveled by radio wave in reaching the two loops.

is used by the Signal Corps SCR-291. Several variations of this device were produced, with different designations, and over 1,000 units were manufactured. On this equipment, the bearing appeared as an elongated figure-of-eight pattern (a twin-leaf pattern) and a line through the points of the leaf indicated the bearing. When the sense antenna was momentarily connected, the leaf pattern changed to a cardioid to resolve the ambiguity.

Fixed errors may occur in any crossed-Adcock system, because of the geometry of the antenna spacing, and are referred to as *octantal errors*. Mechanical goniometers also introduce an octantal error, but these fixed errors may be removed by calibration or by a compensating distortion in the form of presentation. Within a statistical probability of 50 per cent, average bearing errors with DF equipments are about 1.5 deg on ground waves and 3.5 deg on sky waves, respectively. A spaced-loop DF developed by United Airlines prior to the Second World War produced, for many readings, less than 4.5 deg of error for 95 per cent of the bearings and less than 1 deg error for 50 per cent of the bearings. Bearing data are normally classified as class A, class B, or class C for accuracies within ±2 deg,

±5 deg, or more than ±5 deg, respectively; and fixes are similarly classified for accuracies within 5, 20, and 50 miles or more, respectively. Methods of statistical plotting are in use to improve bearing accuracy by averaging or weighing the data produced by the direction finder.[28-30]

36. Loran. The loran system was developed[31] during the Second World War by the Radiation Laboratory in the United States and derives its name from the words "long-range navigation." Its primary purpose was to meet the requirements of military operations and to offer some protection against jamming and enemy use. The choice of frequency, compromising between best accuracy and the longest range, fell between 1,700 and 2,000 kc.

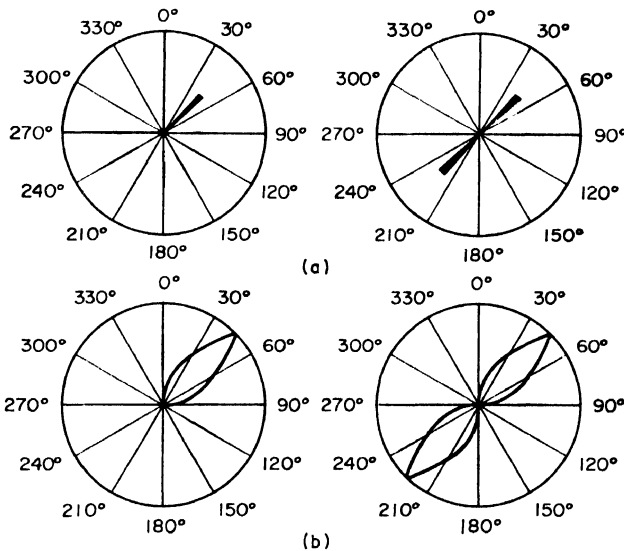
The basic operating principle[32] of loran is the measurement of time difference in propagation between two widely separated transmitting points and the receiving equipment. Since the velocity of propagation of radio waves is a constant, this is


FIG. 19. Typical cathode-ray bearing indications for ground-station direction finders.

equivalent to a measurement of the difference in distance. Loran transmissions are in the form of pulses initiated by widely separated sources, and the difference in arrival time at the receiver is an indication of the distance difference. The locus of points of constant distance difference is a family of hyperbolas; therefore loran is a hyperbolic system.

Athough loran falls short of meeting the requirements of ICAO, its high accuracy and range were recognized by the Special Communications Technical Committee of that organization who, in their meeting during the fall of 1946, urged "that standard Loran, which is now providing important coverage over certain vital ocean areas, be retained and extended or supplemented as may be necessary to meet traffic requirements." By 1954, more than 25 chains employing 53 stations were in operation, furnishing service over a great area of the world, including principally the North Atlantic area and the Central and Southwest Pacific Ocean area.

37. Loran Principles. The loran principle of operation is illustrated in Fig. 20. A chain of stations, providing two sets of hyperbolic position lines, is necessary for a fix. The chain may consist of four stations of which two are masters and two are slaves; or one master may control two slaves, or one slave may be pulsed by two masters. The

maximum practical base line between master and slave is 600 miles, since reliable ground-wave reception (for synchronization of slave with master) is not obtained at greater distances, even over all water paths. A 300-mile base line is conventional. Figure 21 shows a typical arrangement of three stations, with A as the master, for establishing intersecting loran position lines over an area.

Maximum accuracy is obtained when the spacing of lines is closest together and when intersecting lines are perpendicular. Since the longer the base line the greater
FIG. 20. Family of hyperbolic lines of position formed by two antennas 600 µsec apart with the A pulse delayed 700 µsec behind the B pulse.

will be the area for which the loran hyperbolas will be approximately straight and parallel, two properly disposed loran pairs can be used for high-accuracy coverage of an extensive area.

Considering a pair of loran stations, the master station transmits pulses of about 80 µsec duration and of about 70 to 100 kw peak power. Loran designs utilize a repetition rate of 25 or 33⅓ pulses per sec. Pulses from the master station are received at the aircraft after an interval representing the time of propagation. Pulses from the master station are also received at the slave station after some other interval characteristic of the base line used. These received pulses cause the slave station to transmit other pulses at the same repetition rate but with a fixed delayed time. The slave transmission is thus synchronous with the master transmission. Pulses from the slave station arrive at the aircraft after a time interval proportional to the distance from the slave to the aircraft. The aircraft therefore receives two series of pulses and the time interval between these, as measured by suitable time-marker pips, represents the desired time or distance difference.

Loran time intervals are represented in a system of symbols as follows:

T = indicated time difference
L = recurrence interval
γ = coding delay
C = velocity of radio propagation
T' = true time difference
D = absolute delay
β = time taken for pulse to travel from master to slave

All times are measured in microseconds.

Assume that a pulse is transmitted from the master station at $t = 0$. The pulse will arrive at the slave station at a later time $t = \beta$ and the slave pulse will be radiated from the slave station at a still later time $t = \beta + L/2 + \gamma$ which is equal to the absolute delay D. At any receiving point, the true time difference between the master and slave pulses will be $T' = \beta + L/2 + \gamma \pm X/C$ (where X/C is the difference in actual travel time of a radio wave from the master and slave stations to the point). However, owing to the fact that the time difference $L/2$ is automatically taken care of by the presentation of the two pulses in the receiving display, the indicated time difference as used by the navigator will be $T = \beta + \gamma \pm X/C$.

For standard loran, β is usually 1,611 μsec (300 miles) and γ is normally fixed at 1,000 μsec.

38. Loran Receiving and Indicating Equipment. While the specific techniques employed in various receiver-indicator models differ, fundamentally each consists of a conventional radio receiver, a stable oscillator that serves as the source of highly accurate time information, and a cathode-ray oscilloscope on which the received signals are displayed.

FIG. 21. Typical arrangement of three loran stations to form two loran facilities or pairs.

A nonautomatic modern receiver-indicator weighs approximately 40 lb and consumes approximately 190 watts. To receive loran fixes, the receiver must be capable of operating on four different r-f channels. These channels are 1,750, 1,850, 1,900, and 1,950 kc. The superheterodyne receivers utilize crystal-controlled oscillators. The appropriate operating channel is chosen by manipulation of a channel switch. The receiver consists of one stage of r-f amplification, a converter, three i-f stages operating at 1,050 kc, a detector, and one video stage. The total band width, at 6 db down, is 80 kc. The sensitivity is such that a 10-μv signal produces full deflection of the oscilloscope. The image-frequency rejection of the receiver, as well as its response to all spurious signals, is 60 db below the response to the desired signals.

An unusual feature of the receiver is a differential gain control which operates in synchronism with the incoming signal recurrence frequency, and thereby permits different amplification of each of the two signals received from different loran pairs. This feature permits presentation of equal amplitudes on the cathode-ray indicator even with incoming signals having a ratio as high as 500:1.

Selection of the station pairs operating on the same frequencies is done by changing the rate of the oscilloscope sweep. Although all signals will be present on the oscilloscope face, only those signals which are synchronous with the chosen sweep rate will remain stationary. The basic loran repetition rate is varied so as to permit eight choices; therefore the loran

system has provision for receiving and differentiating between 64 different pairs of operating channels at any one time. The first basic rate is 25 pps and is varied by $\frac{1}{16}$ pps per step until the rate of $25\frac{1}{2}$ pps is reached on the eighth step. Similarly, the high basic rate of $33\frac{1}{3}$ pps is varied in steps of $\frac{1}{6}$ pps per step until $34\frac{1}{6}$ pps is realized.

The indicator unit contains the necessary circuits to perform all the timing functions of the equipment with the required precision. The basic timing medium is a precision crystal-controlled 100-kc master oscillator with an extremely high short-term stability. Manual means are provided to vary the frequency by approximately 200 ppm, which permits recycling the oscillator until the timing of the receiver-indicator is in exact step with the pulses received from the transmitting stations. Through the medium of its timing circuits, the indicator provides a sequence of precise timing markers, spaced at convenient intervals, to facilitate measurement of time sequences with a basic accuracy of the order of ± 1 μsec.

The exact character of these timing marks differ with different receiving systems, but the method of measurement involves the sequential rotation of a manual function switch through various positions (from 5 to 7). A typical loran display is shown in Fig. 22 and the operation of the function switch, in one model of a receiver, would be as follows.

FIG. 22. Presentation and interpretation of loran signals. (*U.S. Coast Guard.*)

In position 1, a slow-sweep generator is used wherein each trace lasts for half the recurrence rate; that is, if the ground-station recurrence rate was 25 then the sweep would last for 20,000 μsec and then be repeated. The divider chain also provides a square-wave signal for the vertical plates of the oscilloscope, thereby deflecting the horizontal trace so that one appears above the other. Two vertical deflections are then individually observed on each of the traces representing the received signals from a loran pair of transmitters. A fine frequency adjustment is then made to position the vertical deflections properly and to stop all movement. With the function switch in position 2, fast sweeps are initiated (1,400 μsec) providing a generous expansion of the signals on the face of the oscilloscope. This step also permits differential control of the receiver gain so as to set the two magnitudes to be equal and provides for more accurate time superposition. In position 3, the separation between traces is removed and by use of a fine delay the signals are accurately superpositioned. Thus, the amount of the delay between the starting of the two traces now represents the time between the signals. The remainder of the measurement does not refer to the signals, but only to the locally generated timing signals. Accordingly, in position 4, the radio receiver is no longer in use and the slow-sweep circuit is again reinsti-

tuted in a manner similar to function 1, except that timing marks are superimposed on the display. The presentation appears as in Fig. 23 and the operator counts the number of whole 1,000-μsec marks between the start of the trace and the variable-marker signal. In the example shown, the reading is approximately 6,000 μsec. Finally, position 5 permits a fine measurement of the delay. The fast sweep is again in use but, to permit greater accuracy, the trace is nonlinear. During the first 100 μsec the cathode beam moves rapidly, but during the remaining 1,300 μsec the voltage time slope of the sweep is less steep and the beam moves across more slowly. This last measurement permits the final determination of time interval to within ±1 μsec.

In addition to the five positions described, the receiver normally incorporates a sixth position used for homing. In this operation, the delay controls are first preset to values corresponding to the line of position that is desired; then the aircraft is flown so that the signals on the fast sweep are superimposed.

To obtain a fix, two pairs of stations must be selected and a function switch must be rotated through its positions twice while making the various adjustments. In latest models of loran receiving equipment, further advanced circuits have been incorporated to increase the ease of reading and decrease the time required to obtain a fix. These equipments convert the pulses to sinusoidal waves having fundamental frequencies equal to the recurrence rates of the pulses, after which phase shifters are used to obtain the equivalent superposition. The phase shifters are geared to a number display which indicates the delay directly. The latest model permits making readings on two stations simultaneously.
FIG. 23. Appearance of cathode-ray display with function switch in position 4. The reading is 6,000 + μsec.

Loran charts and tables are published by the United States Hydrographic Office for use aboard ships and aircraft. Each chart shows lines of position for several pairs of transmitting stations, the family of lines for each pair being printed in a distinctive color. These lines are spaced at regular intervals, usually 20 μsec, and every line bears an identification symbol denoting the r-f channel, the basic pulse rate, and the specific pulse rate. The loran tables contain, in tabular form, essentially the same information as the charts.

39. Loran Range and Accuracy. Standard loran signals propagate via ground wave and sky wave, and both types of propagation produce usable signals. Table 3 indicates the signal field strength required to give usable readings for various seasons, latitudes, and times. The table indicates a series of computations for propagation over sea water and shows a maximum range that varies from 400 to 850 miles depending upon conditions of propagation. For transmissions over ground, the maximum distance may be one-half to one-third of the values shown, depending on the conductivity of the soil.

The table values are for propagation via the ground wave only, but loran pulses also travel via the ionosphere and, at night, usable signal strengths are obtained to a maximum of about 1,500 nautical miles. This range is essentially the same over land because only the ground in the immediate vicinity of the transmitter is significant in sky-wave propagation.

Various errors are inherent in the elements of the loran system, such as lack of perfect synchronization between the transmitted pulses (normally ±0.5 μsec), errors in sky-wave contamination, and errors in charts and tables. Furthermore, the area of

Table 3. Range of Loran System

Latitude	Season	Day		Night	
		Required signal, μv/m	Range, nautical miles	Required signal, μv/m	Range, nautical miles
Equatorial	....	25	550	250	400
Middle	Summer	5	700	50	500
	Winter	1	850	10	650
Arctic	Summer	1	850	10	650
	Winter*	1	850	1	850

* The range in winter in quiet regions is limited by the finite sensitivity of the loran receivers.

best accuracy is where the hyperbolic lines are closest together. The positional accuracy may therefore vary over a wide range. In general, aircraft receivers permit readings to about 1 μsec, which, when added to the station synchronization error of about 0.5 μsec, may produce an error of 1.5 μsec. This corresponds to an error of ±788 ft from the proper line of position.

40. SS Loran. This form of loran was an attempt to produce a highly accurate, very-long-range system operating on standard frequencies. Four stations were employed with their base lines intersecting at nearly 90 deg, and all readings were made within the area bounded by a line connecting the four stations. The base lines were 1,000 to 1,400 nautical miles in length. Hence, it was possible to synchronize the chains only via the sky wave, from which the initials SS (sky wave synchronized) were derived. For this reason the system operated only during the night hours. Over most of the coverage, the intersection between position lines from two pairs of stations was over 70 deg; therefore, accuracy was good despite the loss due to uncertainty in the propagation factor. Measured errors varied from 0.6 to 5 nautical miles depending on distance and angle between directions to the stations. No special equipment was required for receiving SS loran in the aircraft. The ground equipment, however, was modified by use of timers incorporating extended delays.

41. Low-frequency Loran. Low-frequency loran was conceived during the last year of the Second World War through the joint effort of the Signal Corps and the Radiation Laboratory of MIT. The system operated at a frequency of 180 kc and comprised four stations located at the corners of a 1,000-mile square to provide a useful coverage of 1,790,000 square miles for day and 1,370,000 square miles for night operation with an rms distance error not exceeding 5 miles. A pulse length of 300 μsec was used, and because of this, it was not possible to match pulses to read the time difference with the same accuracy as with standard loran. The lower accuracy of time-difference readings was compensated, to a certain extent, by the use of longer base lines and by exhibiting the r-f wave on the oscilloscope rather than its rectified envelope. With this system, it was possible to match the r-f cycles and thus increase accuracy.

The summer daytime range with low-frequency loran was 1,000 nautical miles over land and 1,200 nautical miles over sea. The summer nighttime range was more than 1,500 nautical miles. A large number of readings indicated median daytime accuracies of between 1 and 4 nautical miles with distances to 1,500 nautical miles. Similarly, nighttime accuracies of between 1 and 7.5 nautical miles were indicated with distances to 1,500 nautical miles. In both cases, accuracies decreased sharply with distance beyond 1,500 nautical miles.

More recently, receivers have been designed to permit cycle matching of the r.f. and thereby improve the accuracy. This system has been termed "loran B," and receivers of this type are becoming available. The term "loran A" has been applied to the standard pulse-matching loran.

Because the low-frequency loran receiver required a broad band to pass a pulse, there was a question regarding its successful operation in tropical regions. In 1946, ICAO recommended that additional tests be conducted; but before it was possible to do so the International Telecommunication Union at its 1947 conference held in Atlantic City established a frequency of 95 ± 5 kc for use by low-frequency loran and similar systems. In view of this recommendation, it was necessary to redesign all the equipment before tests could be made. By 1954, test results were at hand and at the fifth session of the Communications Division of the ICAO it was recommended that no further consideration be given to the use of this system.[33] However, system development was continued, predominantly for tactical purposes, and this has led in recent years to a type known as "loran C." Loran C is a development of the Sperry Gyroscope Co. and constitutes the only l-f hyperbolic navigation system which is free from sky-wave contamination. This is accomplished by utilizing only the first few r-f cycles of the pulse which always arrive at the receiver prior to the sky wave. A cycle-matching technique is then used to provide an improved order of accuracy. Although still experimental in nature, loran C has shown promise of providing accurate navigation data at ranges in excess of 1,500 miles because of its ability to discriminate against the sky wave.

42. Electronic Pilotage Equipment. Electronic pilotage equipment is the name applied to apparatus heretofore referred to as air-borne radar. The term is intended to apply to air-borne radio equipment that presents in the aircraft a presentation of the terrain below, so that the aircraft may be directed from point to point by an observation of the landmarks appearing on the radio map.[34] Radar of this type was first developed as a means for permitting a night fighter to close in on an enemy bomber and later for target identification in bombing missions. It was first applied in surface detection in about 1941 to locate submarines. Following the war, the equipment was used solely for navigational purposes.

Early equipments were lacking in detail, but were used generally in the following manner. Knowing the starting point, the navigator plotted a course to be flown and noted the time when the first prominent radio-map landmark would appear, and its relationship to the course flown by the aircraft. Data taken from this observation were used to compute a course correction. This dead-reckoning procedure was followed between successive landmarks. With this method, electronic pilotage equipment was useful in spite of its lack of clear detail. Definition was later improved by the use of 3-cm wavelengths instead of the 10-cm then in use.

Equipment was also designed that could be used with ground *transponder beacons*, that is, stations that receive the transmissions from the air-borne equipment and reply by means of a ground transmitter. When used in this manner, the range is limited to line of sight. This application is accordingly not feasible in the long-range en-route zone and the following discussion is limited to unassisted radar.

43. Principles of Electronic Pilotage Equipment. In visual pilotage, the area under observation is illuminated by the sun, and the reflected radiations impinge upon the human eye to form an image which is interpreted in terms of terrain and landmarks. With radio equipment, it is not practical to illuminate the entire area under observation since this would require the generation of prohibitive amounts of power. Instead, the radio energy is concentrated in a beam 3 to 6 deg in total width, and the area is sequentially illuminated by scanning or rotating the beam. At any instant, therefore, reflections are received from a limited area only and, if a 3-deg beam is used, the maximum azimuth definition possible is of the same order. The distance to the terrain objects is determined by transmitting the energy in pulses and measuring the time required for the signal to travel to the object and return. These pulses are of the order of 1 μsec; hence the maximum axial resolution is of the order of 983 ft.

Equipment has been constructed utilizing wavelengths as short as 1 cm, but because of atmospheric absorption, a wavelength of 3 cm has been found to be more practical.

In early radar equipment, one antenna was used for transmitting and a separate antenna used for receiving the reflected energy; however, in all modern equipments the same

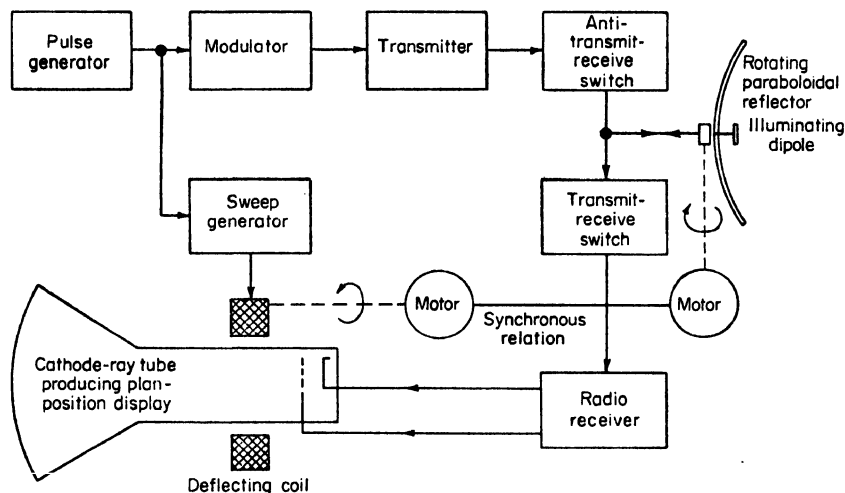
antenna serves both purposes and eliminates possible errors arising from the incorrect positioning of two separate antennas. The principle of electronic pilotage equipment is shown in Fig. 24. The main components of the system consist of a pulsed transmitter, a highly directive antenna system, a receiver, and display apparatus. In Fig. 24, a pulse generator of 1 μsec duration excites a modulator which, in turn, impresses the pulse on the transmitter. Hence the transmitter, operating at 10,000 Mc, generates short bursts of r-f energy concentrated in a narrow beam by the antenna. The direction of the antenna is continuously varied at a rate of about 180 deg per sec. The same pulse used to trigger the transmitter is connected to the deflecting coils of an oscilloscope, after being converted to a saw tooth by the sweep generator. Accordingly, the cathode-ray beam is caused to deflect from the center of the tube to the outermost edge in exactly the time that is required for the radio wave from the antenna to travel to the maximum desired distance and return. The line thus formed can be directly calibrated in distance. As the antenna changes azimuth, the oscilloscope coils are rotated by a mechanism that assures coincidence between


FIG. 24. Block diagram of electronic pilotage equipment.

the position of the deflection coils and the direction of the antenna. A map-type presentation results from which the azimuth of any landmark from a given reference, and its distance, may be directly observed.

In choosing the pulse-repetition rate, the maximum desired range must be considered. A second pulse cannot be transmitted until the first has had time to return by reflection from an object located at the greatest desired range. For a 100-mile range, the maximum p.r.f. would be 920 per sec.

To facilitate the observation of distance, calibration marks equating tube distance to true distance are produced on the face of the tube by electronic means. The definition is limited by the angular beam width, since the minimum width of any spot, regardless of how small the reflecting obstacle, must always be the beam width of the antenna. In distance, or along the axis of the beam, the definition is limited by the pulse width.

Although it may be concluded that electronic means are poorer in definition than visual means, this is compensated to some extent by a much more accurate knowledge of distance and size than is normally offered by visual means. Of greater importance is that electronic pilotage equipment can provide information at night or when weather conditions do not permit visual observation, and can do so at much greater distances than is possible by eye alone.

44. Characteristics and Performance. One of the most common electronic pilotage equipments constructed during the Second World War had an installed weight of about 190 lb, with a power consumption of approximately 1 kw. Subsequent designs have

reduced weight and power consumption, and one of these for commercial-aircraft use weighs approximately 60 lb with a power requirement of approximately 600 watts.

Electronic pilotage equipment in service is capable of detecting cities at a distance of 25 to 50 miles at altitudes of 10,000 ft. It is also capable of detecting recognizable land features such as bays at about the same distance. Mountains may be detected at approximately twice this range depending on their elevation. Typical accuracies of recognizable landmarks are approximately 2.5 deg in azimuth and within 10 per cent of the distance. These accuracies, however, are not the limiting factors in the usefulness of electronic pilotage equipment. For example, over the sea where there are no readily observable landmarks, the equipment is without value except for the recognition of small islands. A typical terrain presentation is shown in Fig. 25. This
FIG. 25. Plan-position display located in aircraft flying in the vicinity of Sandusky, Ohio. (*Courtesy of CAA.*)

presentation may be compared with the map of the same area shown in Fig. 26. Even in cases of terrain with easily recognizable features, it is necessary to interpret the radar map carefully to ensure that features are not being identified incorrectly.[35]

The chief advantage of electronic pilotage equipment is that it is self-contained and therefore has no range limitation. Accordingly it is useful in areas where no other navigational facilities are available. As with any pilotage equipment, its use requires accurate maps.

45. Electronic Aids to Dead Reckoning. Dead reckoning, a term derived from "deduced calculation," is defined[36] as the procedure of determining present position by the addition of one or more vectors representing known courses and distances from some previous fix. This process can be extended to project the known position toward the desired destination. Normally, the process is applied in the following manner. Knowing his present location the navigator determines from a map the distance and direction to the desired destination. The direction to the destination is termed a course and is held by reference to a directional reference such as a magnetic compass. Knowing the speed of the vehicle, the navigator then determines the length of time required to cover the distance to the destination. After the calculated time has elapsed, the navigator may reasonably assume that he is at or near his destination.

This process, when used in an aircraft, has one important exception. Since the pilot is interested in his position with respect to the surface of the earth, the movement of the air mass (winds) with respect to the earth must be taken into consideration in making the calculation. In this case, it cannot be assumed that the heading and course are the same. By taking into account a vector representing the direction and magnitude of the wind, the pilot may compute a "drift-correction angle" that can be added to or subtracted from the "course angle" to obtain a heading to be steered so that the desired track is made good. Although data regarding the magnitude and direction of the wind are usually available, this information is seldom reliable. Winds may change rapidly in magnitude and direction with respect to time, location, and altitude. The pilot therefore follows the practice of making a normal dead-reckoning calculation, but
FIG. 26. Map of area represented by PPI display of Fig. 25.

then corrects it from time to time by observation of his position. This position is determined by observation of recognizable landmarks or by obtaining radio fixes. In this sense, therefore, all radio aids may be considered as electronic aids to dead reckoning. This section is limited to those devices which supply parameters usable in making the dead-reckoning calculation (but do not necessarily give lines of position or fixes) and which are self-contained in the aircraft.

46. High-altitude Radio Altimeter. This altimeter should not be confused with the low-altitude altimeter sometimes referred to as a *terrain-clearance indicator*. Developed during the Second World War to increase the accuracy of high-altitude bombing, the high-altitude radio altimeter saw far more use as a navigational aid than in the application for which it was originally designed. Since the end of the war, this device has become extremely popular, particularly in transoceanic flights.

The high-altitude altimeter is a simple radar which determines distance in one direc-

tion only, namely, directly below the aircraft. Its principle of operation is similar to that described for the electronic pilotage equipment.

In dead-reckoning calculations, the device is used in the following manner. It is known that the direction and magnitude of winds are a function of pressure areas. In the Northern Hemisphere, the winds blow clockwise around a high-pressure area and counterclockwise around a low-pressure area, the converse being true in the Southern Hemisphere. The indication of the barometric altimeter is a function of both altitude and sea-level air pressure; therefore, by determining the absolute altitude through the use of the radio altimeter, the sea-level barometric pressure can be determined. The change in barometric pressure over a period of time describes the pressure system prevailing along that portion of the flight path. While flying at constant-pressure altitude, the radio altimeter is used to determine true altitude at convenient intervals of time. The velocity of the wind component perpendicular to the heading of the aircraft may then be computed by the following formula: $W = K(D_2 - D_1)/A$. In this formula W is the wind velocity in knots, D_1 is the difference in feet between the radio and barometric altimeter noted at the first reading, D_2 is the same difference at the second reading, and A is the air distance expressed in nautical miles. The factor A is derived by multiplying the true air speed by the time between readings. K is a constant varying with latitude and given in navigational tables intended for this purpose.

The principal components of a radio altimeter are a pulse-type transmitter, an antenna system, a receiver, and an indicating device. High-altitude radio altimeters utilize a frequency of 440 Mc. This frequency is sufficiently high to permit generation of short pulse widths and yet allow the use of relatively standard components and techniques.

To avoid the necessity for transmit-receive switches, separate antennas are used for these functions. These antennas consist of simple dipoles mounted $\lambda/4$ below the undersurface of the aircraft fuselage or wings. The $\lambda/4$ spacing reinforces the radiation downward with a gain of approximately 3 db. To minimize drag, the dipoles are normally mounted with their long dimensions parallel to the line of flight. Since the mutual coupling is high for this configuration, a portion of the fuselage must be located between the antennas to act as a shield and reduce the direct transmission between them. If, however, the antennas are located "end on" the coupling between them is essentially zero and no shielding is necessary.

FIG. 27. Appearance of the altitude indication on the cathode-ray tube.

For altimetry, a peak power of from 5 to 10 watts is all that is required; hence the transmitter can utilize receiving-type vacuum tubes. The r-f energy is normally pulsed by two sources, a crystal-controlled source generating a frequency of 98.356 kc and an LC oscillator source generating a frequency of 9.835 kc. The higher frequency produces greater accuracy but presents ambiguities every 5,000 ft which are resolved by the low-frequency source. The ratio of frequencies indicates that no ambiguities are present for the low-frequency transmission within 50,000 ft, which is the service range of the equipment. Pulse widths of the order of 0.25 μsec are used, which correspond to a distance accuracy of approximately 250 ft. This, then, is the theoretical minimum distance at which the altimeter could be used. It should be noted that the pulse-repetition rates are high compared with other types of radar equipment. This is permissible since the maximum distance to be measured is 50,000 ft, which is short compared with expected performance in other types of radar.

A typical altimeter display is shown in Fig. 27. The presentation takes the form of a concentric circle on which two lobes protrude outward toward the edge of the tube.

The first lobe indicates the initial transmission and is located directly upward, while the other lobe, representing the reflected pulse, is at a position which is a function of altitude. A transparent scale calibrates the position with respect to altitude.

The circuit is arranged so that the higher-frequency sweep will always be a little smaller in diameter and thus be readily identified by the operator. A control marked "times one" or "times ten" serves to select the proper sweep. With the fast sweep, a p.r.f. of 98.356 kc is utilized whose period corresponds to the time required for a pulse to travel 10,000 ft. Accordingly, the sweep is calibrated to a maximum of 5,000 ft. For this altitude, the indicator will have made a complete rotation and be coincident with the direct pulse. Because the sweep is continuous, there will be no distinction between altitudes differing by 5,000 ft. To resolve this, the slow sweep is used which utilizes a p.r.f. of 9.8356 kc, which is then read against a 50,000-ft calibration. By reading the scale at the leading edge of the echo during the fast sweep, it is possible to read to within 50 ft regardless of altitude, so long as the aircraft is higher than approximately 500 ft. Considering all errors, the accuracy of the altimeter can be considered to be 50 ft ± 0.25 per cent of the altitude.

A widely used model of a high-altitude radio altimeter weighs 35 to 45 lb installed, and requires 135 watts of power.

47. Doppler Systems. The Doppler drift is a well-known phenomenon in sound and light whose fundamental application, using radio waves, is shown in Fig. 28. In this figure, a radio transmitter is assumed to be located on a moving vehicle A traveling at a speed S in the direction indicated. At some observing point B, the received frequency F_r will differ from the transmitted frequency F_t because of the motion of the vehicle in the following manner.
$$F_r = F_t\left(1 + \frac{2S}{c} + \frac{S^2}{c^2}\right)$$
Normally, the last term is so small that it may be neglected. If the receiving point is located to one side of the direct line of motion, such as point C, then the relative velocity of the vehicle with respect to the observing point will be a function of the angle θ. Under this condition, the following formula holds.

FIG. 28. (a) Transmitter at A travels toward B. The total number of waves passing B is the sum of those for the vehicle at rest plus those carried by because of the vehicle motion. (b) Velocity of vehicle C is a function of the cosine of θ.

$$F_r = F_t\left(1 + \frac{2S\cos\theta}{c}\right)$$

If the observing points reflect energy back to the transmitter, the Doppler frequency is derived by beating a small amount of the original transmitter energy with the reflected energy.

As an example, if a wavelength of 3 cm is employed and the vehicle is traveling at a rate of 300 mph, then the value for $\theta = 0$ gives a Doppler frequency of 8,940 cps. If, however, the transmission from the vehicle is directly at right angles to its line of motion ($\theta = 90°$), the Doppler frequency will be zero. In essence, the Doppler frequency is directly proportional to the rate of closure between the transmitter and the reflecting point.

In the application of Doppler techniques to a self-contained navigation system, two air-borne antennas can be imagined mounted at right angles. The first of these directs a beam of energy along the axis of the aircraft, but pointing slightly downward. The other antenna produces a beam at right angles to the first. By detection of Doppler frequencies along these two axes, both the forward and sideways velocity of the aircraft can be determined. Hence, the actual direction of motion of the aircraft with respect to its heading becomes known.

A single antenna may also be utilized if the antenna is rotated and the components read at different times. This permits a simple modification of existing electronic pilotage equipment. A servosystem is utilized to rotate the antenna with a positional accuracy within 0.25 deg. An additional equipment, weighing not more than 15 lb, then furnishes means for providing drift determination by the Doppler method.

Over reasonably level terrain, drift readings may be obtained with probable errors of the order of ⅓ deg.

As a self-contained navigation system, Doppler techniques may be used to obtain ground speed directly. The method was originally suggested by J. J. Hibbert and N. W. MacLean.[37] Such a device, in conjunction with an appropriate computer, can constitute a self-contained automatic dead reckoner which has the capability of determining present position with respect to a starting point.

48. Inertial Navigation. Inertial navigation was primarily conceived and developed for military applications such as the guidance of long-range missiles and long-range bombing missions. In such applications, its significant advantages include the impossibility of enemy detection (since no radiations are emitted), its independence of ground facilities, and its invulnerability to enemy jamming. Although these advantages are much less important in commercial operations, it is likely that inertial navigation will find future use in civil operations, particularly for long-range overseas flights. Many significant advances have been made in the art of inertial navigation in the past several years, but most of the details of this work, as of this writing, are covered by military security regulations.

An inertial navigator can be considered to be a form of dead-reckoning device, since position is determined with reference to the starting point by proper processing of the data that represent past movements of the vehicle. Basically, the inertial system determines displacement by measurement of the accelerations of the vehicle relative to the earth. In its simplest form, imagine a vehicle equipped with an accelerometer capable of measuring the acceleration of the vehicle along the line of motion. Integration of the acceleration value will yield the velocity of the vehicle. A second integration, operating on the velocity value, will then yield distance traveled. Hence, if the direction is known, the position of the vehicle with respect to the starting point will be established.

If the vehicle is to have unlimited freedom of motion, it is obvious that the acceleration components must be measured in more than one direction. A minimum of two and, in most applications, three accelerometers are required for this purpose which measure the mutually perpendicular components of acceleration. Since it is vital that the accelerometers measure only the acceleration forces on the vehicle and ignore gravity, it becomes necessary to mount the accelerometers on a gyro-stabilized platform so that the direction of gravitational forces will remain fixed and known. By the double integration of the mutually perpendicular acceleration components, the distance traveled by the vehicle in any direction (including the vertical) can be computed and thereby establish an absolute position if the starting point is known.

The principal components of a typical air-borne inertial navigator consist of the accelerometers, a gyro-stabilized platform, a spherical trigonometric computer, and a device to generate special corrections. These special corrections include principally the fact that the earth is not a perfect sphere and the Coriolis effect generated by the rotation of the earth.

At the initiation of the flight, it is necessary to erect the stabilized platform so as to be horizontal and align the accelerometer assembly so that the sensitive axis of the

north-south accelerometer is pointing in the north-south direction. If absolute position with respect to the earth is desired, the latitude and longitude of the starting point and destination must be inserted into the computer. As the flight progresses, the double integration of the accelerometer signals provides the distance traveled in the north-south and east-west directions, respectively. These distances, when added to the starting coordinates, indicate the present latitude and longitude positions.

The system just described makes no allowance for the fact that the earth is spherical and that gyros maintain their position with respect to space rather than with respect to gravity. To provide this additional information and avoid the spurious measurement of gravity acceleration, a device similar to a pendulum is required. An ordinary pendulum, however, is of little use since it would be adversely affected by normal accelerations of the aircraft, particularly for high-speed planes and missiles. This problem is overcome by using the principle first described by Dr. Maximillian Schuler of Germany in 1923. This principle, alternatively called the *Schuler pendulum* or the 84-min pendulum, makes it possible to establish the direction of gravity in a moving vehicle, regardless of its accelerations. In his original description, Dr. Schuler pointed out that a violent deflection of a pendulum in a moving vehicle can be avoided only if the length of the pendulum is equal to the radius of the earth. For example, if the bob of the pendulum were at the center of the earth, it is obvious that the point of suspension can be moved at will without changing the position of the bob. Because the earth is not a perfect sphere, the length of such a pendulum must be varied slightly with latitude. However, this is a second-order effect which is easily compensated for in modern inertial systems.

It is obviously impossible to use a pendulum of the form described above, but the same effect can be obtained by any physical pendulum having a period of oscillation equal to a string pendulum of the required length. This period of oscillation turns out to be approximately 84 min. The effect of an 84-min pendulum is synthesized in the aircraft by a feedback system which utilizes both the gyro and accelerometer signals.

Hybrid Systems. The greatest challenge to the designer of modern inertial equipment is the design of components of greater precision and with reductions in weight. At the present state of the art, an inertial system may weigh anywhere between 75 and 2,000 lb, depending upon the accuracy desired, the length of time involved, and the intended purpose of the mission. Much work is being done on increasing the sensitivity and accuracy of accelerometers and gyros to make possible more precision and less weight. At the present, these components have proved difficult both in development and in manufacture, and are extremely costly. A pure inertial system of sufficient accuracy to be reliable as a long-range navigation aid still weighs many hundreds of pounds. To overcome this problem, many observers have suggested the use of a "hybrid" system in which the inertial navigator is combined with other forms of navigation. These hybrid combinations are practical with any self-contained or dead-reckoning equipment and are not exclusively limited to inertial navigators. The hybrid equipments can utilize a supplemental radar, celestial observation, or radio ground-reference techniques to correct occasionally the cumulative errors which build up in pure inertial or dead-reckoning systems.

One example of a hybrid system is the use of a Doppler radar to measure the ground speed of the aircraft. This is then compared with the first integration of the inertial equipment, and if any steady-state errors exist a correction is made in the inertial equipment. Such a system can be used even under military conditions since the Doppler radar would be required only for a few seconds at intervals of perhaps 10 or 15 min. Another possibility is the combination of celestial and inertial navigation in which a fix is obtained by the use of a sextant. One such sextant has been developed which provides for automatic tracking of preselected stars or planets by night or the sun by day. This system is useful at high altitudes where celestial observations may always be made irrespective of weather. A third combination is the use of any ground radio-navigation system capable of providing a fix of the desired accuracy. This would avoid the necessity for continuous operation of civil-navigation aids in the event

of a major war, and thereby avoid the use of these aids by enemy bombers. When combined with an inertial-navigation system, aids such as VORTAC or Tacan could be turned on briefly at irregular intervals to enable a pilot to reset his inertial navigator and avoid cumulative error. A similar arrangement could be used with long-range navigation aids such as loran and Navarho. Engineers believe that an inertial navigator of limited accuracy weighing of the order of 30 to 40 lb could be constructed for use in a hybrid system.

In summary, inertial navigators are capable of supplying the following information without radiation of signal and without reference to ground aids.

1. The geographic position of an aircraft in latitude and longitude, or as a function of the distance and direction from any starting point
2. The ground speed and track
3. The distance traveled from the starting point and the distance remaining to the destination
4. The direction of the destination
5. The attitude of the aircraft

As an obvious extension, it should be noted that the gyro-stabilized platform can be used for other purposes such as the control of an automatic pilot, the stabilization of radar antennas, and as a precise reference for heading instruments. Thus, a coordinated instrumentation in the aircraft could save appreciable weight. However, in spite of much progress to date, many problems still exist in the development of accurate and reliable components, and it is generally agreed that inertial navigators for common civil use are many years in the future.

PART 2

THE EQUIPMENT OF THE EN-ROUTE SHORT-DISTANCE ZONE

49. Requirements. The en-route short-distance zone has been defined[38] as that portion of the airspace in which the long-distance en-route zone terminates, and which is served primarily by radio aids spaced at intervals of less than 200 miles. The en-route short-distance zone in turn terminates in, but it does not include, the approach or airport zone. Unlike the long-distance zone, the primary problem of the short-distance zone is that of traffic control. This occurs because of the convergence of traffic in the short-distance zone which rises to a maximum density in the approach zone.

Normal traffic-control procedures in the en-route zone consist in reserving a block of airspace for each aircraft. This procedure may be formal, where clearances are filed with a ground governmental agency, or may be informal where only flight advisory services are employed. Whichever procedure is used, a successful traffic-control system must be capable of making reservations with sufficient rapidity so that the movement of an aircraft into the desired space can be made without delay.

A primary requirement of navigational aids in a short-distance zone is that they shall be capable of providing guidance along the shortest possible route. Accordingly, full airspace coverage is preferred as opposed to discrete courses or airways. This provides maximum air safety in traffic control since the location of the aircraft is known anywhere in the short-distance zone.

A second important requirement, relating to traffic control, is that sufficient accuracy[39] must exist to define adequately the boundaries of the reserved airspace. From another point of view, greater accuracy permits a reduction in the dimensions of the reserved airspace and thereby permits a higher traffic density with safety.

A third important requirement of short-distance navigational aids is that they must furnish guidance at all times, even under adverse atmospheric conditions. In high

traffic densities, loss of guidance for even short periods greatly increases the dangers of collision. To complete the requirements for safe traffic control, rapid and reliable communications is also vital.

In summary, a short-distance navigational aid must provide complete airspace coverage with sufficient accuracy to control safely the expected traffic density, and incorporate, if possible, reliable communication service.

50. The V-h-f Phase-comparison Omnidirectional Radio Range (VOR). Historically, the work which led to the modern VOR was begun in about 1928 by Englund,[40] Evans,[41] and Greig[42] of the Bell Telephone Laboratories. Although their work stopped in 1930, interest in the device was revived by the work of Dr. D. G. C. Luck[43,44] which began in about 1937. In 1940, CAA undertook the continued development of VOR, which extended through the Second World War. The outcome of the development[45] was presented to the RTCA at a meeting in January of 1945.

In 1946 the United States government offered VOR for worldwide use in the en-route short-distance zone at a meeting of the Special Communications Division of what was then the PICAO. The device was accepted by this organization, as indicated by the following excerpt from Annex 10 of the Standards and Recommended Practices of the ICAO: "In localities where conditions of traffic density and low visibility necessitate a short distance radio aid to navigation for the efficient exercise of air traffic control, the standard aid shall be the VOR (VHF Omni-range) of the CW phase-comparison type conforming to the standards contained in paragraph 3.4 of Chapter 3 of this Annex."

51. VOR Principles. The VOR principles of operation are similar in many respects to the CAA l-f omnidirectional range discussed in Sec. 25. In brief, the operation of the VOR may be likened to that of an airway light beacon revolving at a uniform rate. If the beacon makes 1 rpm, and if a fixed red light on the beacon tower is caused to flash as the beam points north, an observer with a stop watch can determine his bearing merely by starting the watch when the red light flashes and stopping it when the beam flashes past him. The azimuth angle measured from north is then directly proportional to the time recorded by the stop watch.

The omnirange functions through the radiation of two separate r-f field patterns generated by a common transmitter. The first, or variable-phase pattern, corresponds to the rotating beam of the beacon, while the second provides the signal reference and corresponds to the flashing red light. These field patterns are produced by an antenna array consisting of four horizontal-loop-antenna elements of the Alford[46] type located at the corners of a square, and a fifth element located at the center. The center element is excited with v-h-f energy in the 112- to 118-Mc range. The r.f. is amplitude-modulated approximately 30 per cent with a 9,960-cps signal. The 9,960-cps signal is, in turn, frequency-modulated with a 30-cps reference signal with an excursion of ± 480 cps. In addition, voice modulation not exceeding 40 per cent may be applied to this same carrier. Accordingly, the central element produces a nondirectional reference field pattern which also serves as a voice channel.

The diagonally disposed pair of elements at the corners of a square are connected to a common feed point by different lengths of transmission lines so that one element is 180 deg out of phase with the opposite element. The radiated pattern is thus a figure of eight. The same arrangement is employed with the other pair of antennas diagonally disposed on the other two corners of the square. The transmitter supplies energy to these two pairs of antenna elements through a special capacitor-type goniometer, the rotor of which is driven at 1,800 rpm (30 rps) in phase synchronism with the reference generator. The goniometer functions like two mechanical side-band generators, suppressing the carrier and feeding two 30-cps modulated side bands (displaced by 90 deg in phase of the modulation envelope) to the two pairs of antenna elements.

Since the modulation envelopes of the individual patterns are in phase quadrature, the resultant produces the equivalent of a rotating field. This field, when combined with the carrier of the central antenna, forms a limacon pattern. At any observing point, the rotating limacon pattern, when demodulated, produces a 30-cps signal which constitutes the variable-phase term. The demodulation of the f-m 9,960-cps tone

produces the reference 30-cps component. With proper calibration of the ground and air-borne equipment, phase comparison of these two components yields the bearing of the aircraft from north.

52. VOR Equipment. The antenna array developed by CAA is illustrated in Fig. 29. The four coplanar loops are mounted at the corners of a square such that the diagonal or spacing between opposing pairs is 112.2 electrical degrees. The four antennas occupy positions approximately 48 in. above a counterpoise while the central antenna is mounted on a pedestal $63\frac{3}{8}$ in. above the counterpoise. With this spacing of 112.2 deg, octantal variation of about 2.5 deg in phase will occur. This error may double if the two side-band voltages differ in amplitude by as much as 10 per cent.

FIG. 29. (a) CAA antenna array using five Alford loops. (b) Plan view of CAA VOR antenna array.

A block diagram of the VOR system is shown in Fig. 30. The essential components are a v-h-f transmitter, a voice and reference modulator, a goniometer, the f-m reference generator, and the antenna system previously described. The c-w transmitter is crystal-controlled and operates in the band from 112 to 118 Mc. Transmitters have been designed with various power outputs ranging from 50 to 300 watts. An important requirement is that the transmitter shall be capable of 100 per cent modulation from 300 to 12,000 cps and that there shall be no phase shift with modulation from 9,480 to 10,440 cps. When voice is used for station identification, it is recorded on film that is moved continuously by a motor, and repeats the identification at intervals of between 10 and 20 sec. A second method of identification is a 1,020-cps tone keyed with International Morse code signals.

The principle of the rotating capacitor-type goniometer is shown in Fig. 31. Two rotor plates, insulated from each other, form half cylinders with the ends tapered. When rolled out flat the shape of each plate is equivalent to double half-sine waves. Two sets of stator plates, each stator consisting of two insulated half-cylindrical shells, are disposed side by

FIG. 30. Schematic of transmitter for VOR.

side about the rotor, so mounted that they are displaced by 90 deg. V-h-f voltage from the transmitter is applied across the two rotor plates and each stator feeds one pair of differentially connected antenna elements. The capacitor goniometer produces two v-h-f outputs proportional to the sine and cosine of the displaced angle of the rotor, respectively.

The reference generator consists of a tone wheel driven from the same motor that rotates the goniometer, thereby ensuring perfect synchronism between the variable phase and reference tone. The teeth of the tone wheel are made of magnetic material and are swept by the pole piece of a permanent magnet. The teeth have variable spacing to generate in the coil a nominal frequency of 9,960 cps modulated at a 30-cps rate. This subcarrier, already frequency-modulated, is then applied as amplitude modulation to the carrier. An alternate method is to generate a synchronous 30-cps tone which then frequency-modulates an independent 9,960-cps oscillator. The tone-wheel method, however, offers the advantage of increased stability and reliability.

An alternate antenna system of novel design was developed by the Federal Telecommunications Laboratories[47] for use with VOR. The purpose of the development was (1) to minimize the difficulty of installation and adjustment by reducing the number of transmission lines to the antenna system, (2) to reduce octantal error by physically (rather than electrically) rotating the field pattern, and (3) to reduce polarization error by a structure of special design.
FIG. 31. Rotating-capacitor type of goniometer for v-h-f omnirange.

Briefly, the structure consisted of two cylindrical cagelike structures made of vertical rods. The lower structure, approximately 6 ft high, is the source of both the reference-phase and variable-phase field patterns. The upper structure, approximately 12 ft high, serves the purpose of suppressing the unwanted or vertical polarization component and has no electrical connections to the transmitter. The diameter of the system is approximately 30 in. Electrical connections within the structure are made by means of a circular wave guide. A dipole of $\lambda/10$, internal to the lower structure, is rotated by a small synchronous motor to obtain the desired pattern rotation.

53. The VOR Receiver. Omnidirectional-range receivers designed for commercial service are crystal-controlled and provide preset channels every 100 kc. Since some receivers provide as many as 280 channels, these receivers incorporate crystal-saving schemes to eliminate the necessity for employing a crystal for each channel. As typical examples, the Federal Telephone and Radio type 145 receiver employs a triple superheterodyne to achieve the desired performance with 21 crystals for 140 channels. The Collins 51-R receiver is a double superheterodyne and employs 34 crystals to produce 280 channels.

The sensitivities of commercial receivers are such that an input signal of 3 μv, modulated 30 per cent with a 1,000-cps tone, produces 200 mw of output with a signal-to-noise ratio of at least 6 db. AGC maintains the signal constant within 3 db for signals that vary from 5 to 50,000 μv.

The primary function of the receiver is to recover the reference and variable-phase 30-cps components so that they may be compared to yield the bearing of the receiving point with respect to the omnirange station. A further function is to provide course indications suitable for flying a course along the radial corresponding to that bearing. A

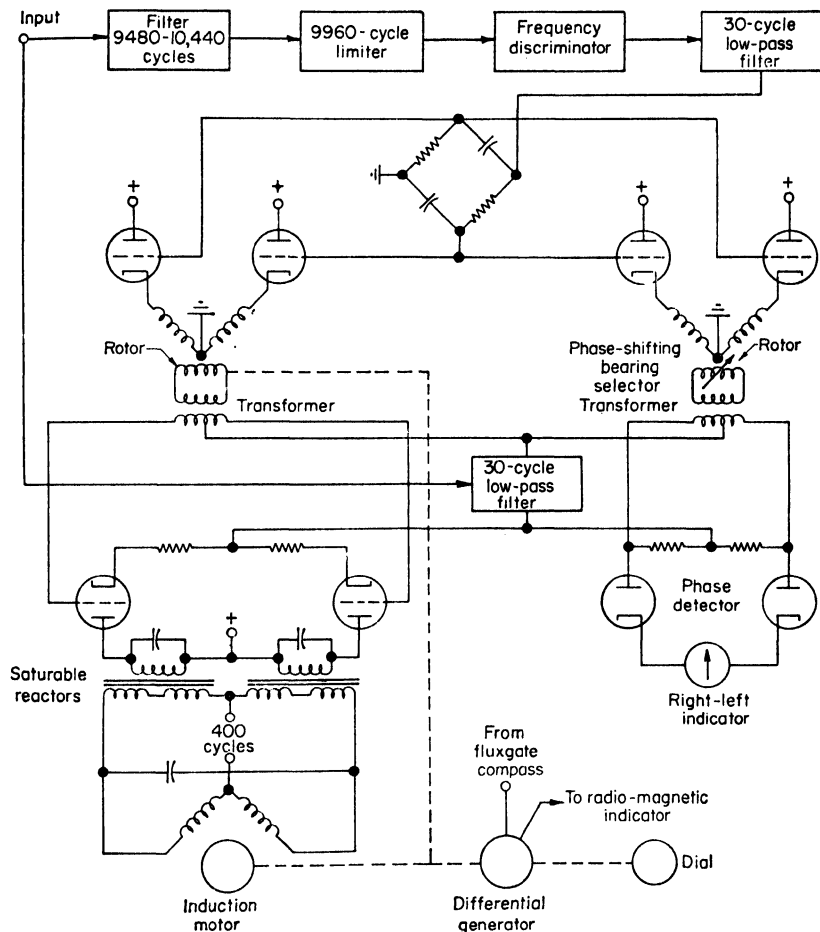
typical circuit to provide this service is shown in Fig. 32. The reference signal is separated from the complex audio signal by a 10,000-cps filter. After limiting, frequency demodulation, and further filtering, the reference 30-cps tone is fed to a phase splitter that produces two outputs of 90 deg phase relation. These outputs are then fed to the stationary coils of phase shifters. One of these phase shifters is driven by an induction motor to provide an automatic indication, while the other is operated manually and is called a *bearing selector.*


FIG. 32. VOR bearing-indication circuit.

The 30-cps variable-phase component is recovered by amplitude demodulation and, after filtering, is fed to a phase detector whose reference is obtained from the manually operated phase shifter. The output of the phase detector operates the vertical needle of a cross-pointer instrument. When the bearing of the aircraft from the ground station is equal to the bearing that has been set on the bearing selector, there is no deflection of the needle. By following right or left deflections of the needle, a radial course may be flown to or away from the VOR station. In general, the sensitivity is set so that a variation in bearing of 30 deg causes a full-scale deflection from right to left.

The output of the motor-driven phase shifter goes to a second phase detector whose output controls two saturable reactors connected in series with the windings of a split-

phase induction motor. The motor is therefore energized until the reference and variable-phase signals are in phase. The position of the shaft is read on a dial and represents the relative bearing between the VOR station and the receiving equipment.

To provide an RMI (*radio magnetic indicator*) (Sec. 73), a differential generator is utilized in the circuit. The rotor of the generator is connected to the output of a flux-gate compass. The card on the RMI indicator, calibrated from 0 to 360 deg, rotates as a function of the magnetic bearing of the aircraft. This bearing may be read against a fixed lubber line located at the top of the instrument. The needle is rotated in accordance with the output of the differential generator. The compass card and needle rotate together for a change in aircraft heading, assuming that there has been no change in the bearing of the aircraft from the range station. For a change in bearing, but not in heading, the needle alone moves. Therefore, if the pilot desires to fly directly to the VOR station via the shortest route, he alters the heading of the aircraft until the range needle points to the lubber line.

Without an RMI indicator which exhibits bearing from 0 to 360 deg, a possibility of ambiguity exists. Using only the manual phase shifter and the cross-pointer indicator, a zero indication is obtained at two points representing reciprocal courses. To resolve this ambiguity, a to-from indicator is normally supplied to distinguish between the direct and reciprocal courses. When flying over the station, this indicator deflects from "to" to "from."

In addition to providing the indications required for short-range navigation, modern VOR receivers are also capable of receiving transmissions from runway ILS localizers of either the equisignal or phase-comparison type. Moreover, the same cross-pointer indicator also serves during the approach to indicate the localizer and glide-slope paths.

A number of receiving antennas of different designs[48] are in use, the simplest being a horizontal V-type dipole with an 80-deg apex angle and fed by a coaxial line. Another common type is the U or *ram's-horn* antenna which consists of two members with streamlined cross sections forming a horizontal U. These are mounted on a pedestal somewhat less than $\lambda/4$ above the fuselage. The pedestal includes a matching transformer. Other designs[49] are available for high-speed aircraft which feature very low aerodynamic drag. A preferred mounting position for the VOR antenna is atop the vertical stabilizer, where attitude effect and propeller modulation have been found to be minimum.

54. Range and Accuracy of VOR. The range of VOR is limited by radio line-of-sight considerations and, even with aircraft of high-altitude capability, does not extend beyond 200 miles. For aircraft of the commercial type, the range can be considered to be of the order of 100 miles.

The bearing accuracy of the VOR system is limited by six main sources of errors, which are listed below.

1. Ground-station octantal error
2. Receiver-indication error
3. Polarization error
4. Vertical-pattern effects
5. Site effects
6. Terrain effects

The first three errors can be classified as equipment errors while the last three can be considered propagation effects.

The ground-station maximum octantal error is 2.5 deg for the standard CAA antenna system. Although the Federal antenna should theoretically produce no octantal error, in practice it exhibits an error of 1.75 deg.

Receiver-indication errors are produced from such factors as unequal phase shifts in the receiver channels for the variable-phase and reference-phase signals, errors in the phase detector, and inaccuracies in the resolver. These errors exhibit a slow systematic variation with bearing and may vary with individual receivers and with aging of components. In typical receivers, the maximum value of these errors may be between 0.5 and 1.0 deg.

Polarization errors occur when the vertical field component of the ground transmission is excessive. These errors have been termed *course push* or *attitude effect*. These names stem from the fact that bearing changes are noted if the aircraft is banked, so that its receiving antenna becomes more efficient in receiving vertically polarized radiations. The error results since the vertically polarized component, being of an uncontrolled nature, is not likely to contain the same modulation information as the desired horizontal component. To reduce polarization error to the order of 0.1 deg the vertical field reception should be suppressed approximately 60 db below that of the horizontal field. Typical flights performed by the CAA have shown attitude errors ranging between 1.5 and 2.6 deg.

The field strength produced by any antenna system mounted above ground is dependent upon the sum of two components, the direct component, and the component derived from reflection from the ground. At some points in space, these components are out of phase and produce a signal minimum. The number of such lobes is a function of the electrical height of the radiator above the ground plane. When flying in the vicinity of these minima, momentary loss of signal results. When the signal coming directly from the range station reaches a low value, other signals reaching the receiver via reflection from nearby areas (and which are normally insignificant) assume a major importance. The result is a possible departure of the bearing indication from its true value, and these errors are classified as *site* or *terrain errors*.

Site effects and terrain effects may vary widely in error depending upon the site chosen. The VOR system produces indications within accuracies of ±1.5 deg on radial courses free from serious reflections. In general, properly installed VOR facilities can be expected to produce total accuracies of better than ±5 deg.

55. The VOR Monitor. The CAA does not permit the use of equipments as navigational aids in blind flying unless the equipment is adequately monitored and unless a fail-safe alarm indication is presented to the pilot. On the ground, the monitoring system consists of a remote receiver and phase-comparison unit. This receiver, normally similar to the air-borne design, is housed in a weatherproof case and located approximately 200 ft from the station. The monitor measures all significant quantities in the transmission, and a deviation beyond acceptable limits of these quantities energizes an alarm and causes stand-by equipment to be actuated. In the aircraft, absence of the complete signal (or any component of the signal) actuates a flag alarm.

56. Distance-measuring Equipment. An adaptation of wartime radar, DME enables a pilot to determine his distance from a transmitting station. The device saw its beginning as intercept equipment on aircraft early in the Second World War. During the use of this early equipment, it was found that a beacon (or transponder) located on the ground could be used in conjunction with air-borne radar to furnish valuable navigational information. These transponders became necessary since the v.h.f. then employed for intercept purposes did not permit distance reading at low altitude by pure radar reflection. One of several early systems was known as **BABS**, and was derived from "blind-approach beacon system."

The usefulness of distance indications led to the development of special systems which used the combination of air-borne radar interrogators and ground transponders exclusively for navigational purposes. Experience gained illustrated the advantages of a distance-direction presentation (polar navigation) in which the frame of reference was a point on the earth. It was evident that such a system permitted the convenient generation of an unlimited number of fixed flight paths. From this background, engineers of the Wright Air Development Center of the United States Air Force therefore urged[50] the development of a distance-measuring equipment that could be used in conjunction with the v-h-f omnidirectional radio range being developed by the CAA.

The advantages of distance-measuring equipment were recognized by technical representatives of other nations, and a recommendation[51] for such equipment was made by the Special Radio Technical Division of the ICAO that met in Montreal in November of 1946.

In 1949, ICAO recognized u-h-f DME in its Standards and Recommended Practices

with the following paragraph appearing under the recommendation for short-distance radio aids. "It is intended that UHF-DME . . . will become a basic component of the VOR . . . at the earliest date practicable, to be added to all VOR which have been installed before that date."

During the interval, successful distance-measuring equipment had been constructed operating in the 200-Mc range. Although the ICAO standardized on this frequency band, it left room for the use of 1,000-Mc equipment by including a developmental specification for DME operating in the 960- to 1,215-Mc range.

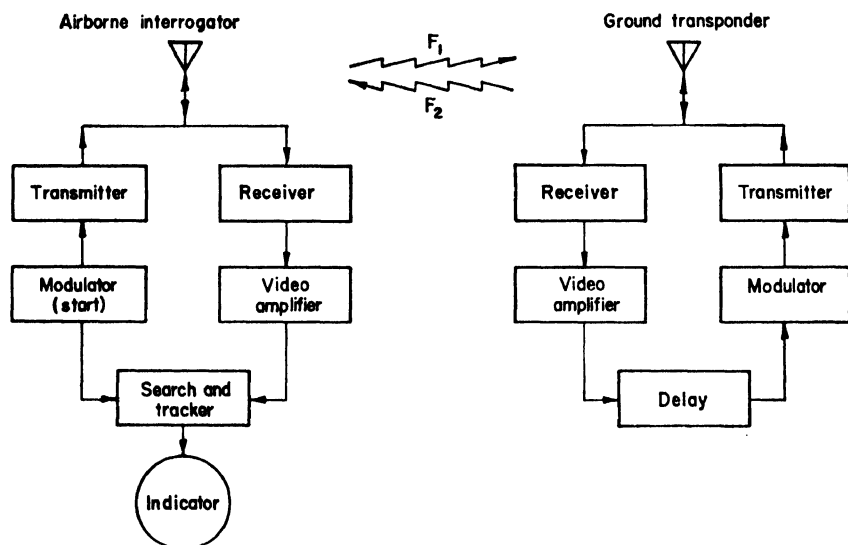
CAA policy is to add DME to all VOR and ILS stations. This equipment, operating in the 960- to 1,215-Mc band, uses both frequency and pulse coding to identify the individual channels. This system, normally referred to as the "civil DME" or "CAA-DME," is described below. Another existing system is the Tacan-DME (sometimes called "DMET"), whose significant difference is that channeling is


FIG. 33. Distance-measuring system consisting of air-borne interrogator and ground transponder.

accomplished by frequency separation only. For details of Tacan, see Sec. 71. Since the two systems utilize the same frequency range but different channeling, they were incompatible for use in a common ground environment. Accordingly, in the fall of 1956, the Air Coordinating Committee recommended that the Tacan-type channeling be standardized for use in the United States. When combined with the VOR, this has been termed VORTAC. The description that follows, except for channeling and certain specific equipments, applies equally to both systems since the principles of operation are identical.

57. Principle of DME. The DME principle is illustrated in Fig. 33. The system consists of air-borne equipment known as an interrogator and ground equipment referred to as a *transponder* or beacon. The process begins in the air-borne interrogator by the generation of omnidirectionally radiated pulsed transmissions at a frequency F_1. The pulse-repetition rate is relatively low and seldom exceeds 150 per sec. These pulses are usually generated in pairs for reasons that will be explained later. The pulses are received by the ground beacon and, after a fixed delay time, are used to trigger the transmitter of the ground transponder. These response pulses are also radiated omnidirectionally but on a frequency F_2. The response pulse is then received by the air-borne equipment and the time of reception is measured relative to the time of initial transmission of the interrogator pulse. This time

interval is directly proportional to the distance between the aircraft and the ground beacon. Hence, the basic measurement is the round-trip radio-propagation time (plus some fixed delays) between the aircraft and the beacon.

Since many aircraft may be interrogating the same beacon, it becomes necessary for the aircraft to distinguish its own reply pulses from many others. This is done by searching for and utilizing those pulses which are synchronous with one's own interrogation transmissions. Accordingly, the search and tracking unit examines all signals and chooses those which have a fixed time with respect to the transmitted signals. The air-borne modulator is designed with an intentional jitter in the repetition rate, so there is little probability that several aircraft can continue to send pulses at exactly the same rate. After the search and tracking unit locks on these synchronous reply pulses, it continually measures the time that elapses from the time of transmission to the time of reception. This action concludes the "search phase" of the equipment and initiates a "track phase" in which the pulse-repetition rate of the interrogations is greatly reduced. This operation reduces the load on the transponder and permits a larger traffic capacity. The time measurement is converted, by suitable instrumentation, to a direct reading of distance in miles.

58. Frequency and Channeling of DME. As mentioned previously, frequencies in the 200- and 1,000-Mc ranges were considered for distance service. An important factor in the ultimate choice was the band width required for pulse transmissions. Distance measurement demands short pulses for accuracy. The half-power band width in megacycles for a square pulse of t μsec duration is equal to $1/t$. Hence, pulse lengths of 2 μsec require a channel width of the order of 1 Mc with some guard space. In the 200-Mc band, modern techniques permit practical selectivities of the order 50 to 100 kc; hence, this band can accommodate many high-information voice-communication channels.[52] At 1,000 Mc, however, the state of the art is such that channel spacing cannot be much less than 1 Mc. Thus for whatever purpose the channels at 1,000 Mc are applied, the channel spacing must be of the order of 1 Mc to avoid interference. Therefore, in view of the need for conserving radio frequencies, the wide spectrum required for distance measurement is more advantageously obtained at 1,000 Mc. This factor, coupled with others involving propagation characteristics and antenna sizes, led to the international standardization of the band from 960 to 1,215 Mc for navigation use.

In determining the number of channels required, the principal factor is the minimum distance at which stations can be located without interference and still supply over-all area coverage. Modern aircraft, flying at altitudes of 40,000 ft, have a radio horizon of approximately 280 miles. It is impossible, however, to space the DME facilities at 560 miles and still supply signals to low-flying aircraft. Accordingly, stations are normally spaced at intervals of approximately 100 miles and sufficient channels must be provided to avoid interference. The problem is further intensified by the addition of DME service to ILS installations.

Cognizant agencies in the United States originally felt that 50 channels would provide adequate service on a noninterfering basis. In the interim period, it was found that this number of channels was insufficient, and present requirements call for at least 100 distance-measuring operating channels. For distance service an operating channel really consists of two channels, one to carry the interrogation from air to ground, and the other for the reply from ground to air.

Two general methods are available for providing these operating channels, namely, the clear-frequency method and the pulse-multiplex method. In the first method, as in Tacan, a 1-Mc channel spacing is utilized, thereby providing 126 two-way clear-frequency channels.

The pulse-multiplex method[53] is employed by the CAA-DME. With this method, each channel employs a combination of frequency and double-pulse codes to distinguish between channels. The pulse code consists of a pair of pulses of certain spacing. These spacings (or modes) are specified by ICAO as 14, 21, 28, 35, 42, 49, 56, 63, 70, and 77 μsec. The same spacings are used for both ground and air transmissions, except that the order is reversed. Accordingly a widely spaced interrogation mode is coupled with a narrowly spaced reply mode and vice versa. These 10 modes can be

associated with any one of 10 frequencies to provide the required 100 two-way channels. These frequency channels are 2.5 Mc wide and are centered, for air-to-ground interrogations, from 963.5 to 988.0 Mc and, for ground-to-air replies, from 1,188.5 to 1,211.0 Mc. As mentioned previously, the ACC decision of 1956 has brought about the decommissioning of the pulse-multiplex DME, and the CAA has scheduled implementation of co-located VOR and Tacan equipments which constitute VORTAC.

59. DME Apparatus. Early DME equipments with relatively wide channel spacings used cavity-stabilized oscillators as the r-f source. Crystal-reference control was introduced later. All modern DME equipments, however, utilize direct crystal control in both the ground and air-borne components. The technique[54] involves frequency multiplication from a crystal-controlled oscillator operating at a subharmonic of the desired output frequency, and lends itself readily to the use of standard vacuum tubes. Peak power outputs of from 6 to 20 kw have been so obtained with a frequency stability of better than 0.01 per cent.

The transponder antenna must be capable of transmitting in the frequency range from 1,188 to 1,211 Mc and simultaneously receive interrogations from 963 to 988 Mc. This virtually means that the antenna must operate over the complete range from 960 to 1,215 Mc. Other requirements of the antenna include vertical polarization, a circular radiation pattern in the horizontal plane, and a power gain in the vertical plane of the order of 8. It is also desirable that the vertical pattern be pointed slightly upward from the horizontal.

One such antenna employs a number of *discone* elements. A discone consists of a metallic cone having an apex angle of about 60 deg and a metallic disk located adjacent to the apex. When fed by coaxial line, the inner conductor may be connected to the cone and the outer conductor to the disk. The discone behaves essentially like a vertical dipole, except that its impedance stays fixed over a wider frequency range.
FIG. 34. Discone ground-transponder antenna.

To obtain a power gain of 8 and a beam that is tilted slightly upward, discone elements are stacked as shown in Fig. 34. The individual transmission lines from each discone are connected in parallel at a common junction box, and by means of a $\lambda/4$ transformer, the impedance is rematched to that of the single coaxial transmission line from the transmitter. Mechanically, the individual antenna elements are mounted in a Fiberglas supporting structure, and the entire array is housed in a weatherproof Fiberglas enclosure.

Other essential components of a transponder include a pulse modulator and receiver. The main function of the modulator is to process the interrogation pulses from the receiver so as to apply the desired double-pulse spacing in accordance with the mode selected. A nickel delay line, on which a number of taps or pickup coils are provided, is utilized for the generation of the pulse codes. The input pulse is connected to a pickup coil located at the extreme end of the line and is simultaneously connected to the proper coil for producing the delay defining the particular channel on which it is desired to operate. The pair of pulses so produced are regenerated so as to restore the desired pulse width, and the pulse-pair output triggers the r-f transmitter. The receiver used for the air-borne interrogator and the ground transponder are quite similar in principle, and the following description applies to both.

At the input to the receiver, a series of cavities are used for r-f preselection. In the multiplex-channel system, the separation between the transmitting and receiving frequencies is at least 200 Mc. Hence the former is readily prevented from reaching the receiver and all undesired responses are attenuated by at least 60 db. The remaining r-f portions of the receiver are conventional in nature. The i-f band width is normally 6 Mc, with a channel spacing of 2.5 Mc. To reject adjacent channel transmissions, use is made of a circuit normally referred to as a *Ferris discriminator.* The action of this circuit is shown in Fig. 35. The i-f amplifier has been designed so that adjacent channels are passed

without too much attenuation. Figure 35*A* shows the response of the discriminator as a function of frequency. Similarly, Fig. 35*C* shows the response resulting from a pulse on an adjacent channel. The video circuits following the Ferris discriminator respond only to a negative input. A strong negative pulse occurs only when the pulse spectrum lies centered in the Ferris pass band as shown in Fig. 35*E*. The Ferris discriminator is also useful in the suppression of ignition noise and acts somewhat as a spike suppressor.

The a-g-c requirements are quite different for the transponder as compared with the interrogator. The air-borne receiver attempts to receive emissions from a single transmitter whereas the transponder must be capable of receiving many signals originating anywhere within the 100-mile range of the beacon. In addition, the ground-receiver gain must be controlled to prevent overloading in the ground transmitter.
FIG. 35. (*A*) Ferris discriminator response. (*B*) For pulses two channels below the tuned channel, the video wave form is a positive low-amplitude pulse. (*C*) For pulses one channel from tuned channel, the video output is a large positive pulse and two small negative pulses. (*D*) With pulses one-half channel off, the video output consists of two small negative pulses. (*E*) Pulses on the desired channel produce a video output consisting predominantly of a large negative pulse which is passed by the following video stage.

In the case of an interrogator operating on a clear channel, that is, without pulse multiplex, the problem is relatively simple. The AGC is designed to allow normal receiver operation at high sensitivity with a relatively short recovery time. The AGC is controlled solely by those pulses which constitute replies to the particular interrogator. In the case of pulse-multiplex channeling, it is only after decoding that spurious replies are segregated. For the ground receiver utilizing the pulse-multiplex channeling, the receiver is set to have a high sensitivity and designed for rapid recovery. Some of the noise from the receiver is rectified to form approximately 300 pps, and these are supplied to the transmitter. The output of the transmitter is monitored and when the number of pulses reaches 2,000 pairs the gain of the receiver is reduced so that the transmitter cannot be further loaded. This type of control is referred to as *automatic gain stabilization* and *automatic overload control.* A third feature incorporated in the ground receiver is called *echo suppression.* It often happens that interrogations are received by a direct path as well as by reflection from nearby objects. The latter pulses are called echoes and combine with the main pulse to produce a widened pulse. The echo-suppression circuit serves to reduce the gain of the

receiver immediately after the reception of a pulse, but restores the gain of the circuit to normal shortly thereafter.

The principal measuring component of the air-borne receiver is the ranging circuit, or *strobe*. A number of automatic ranging circuits have been employed using a combination of electronic and mechanical techniques. In general, a strobe utilizes delayed gates which are generated by the original interrogations and searched in time for reply pulses. The proper reply signal is identified as a series of pulses coincident in time with the gate. Because of the intentional instability incorporated in the interrogation rates, unwanted replies would not be synchronous with the gate and would therefore appear only occasionally.

Four operations are provided in air-borne DME that automatically and continuously display distance information. These are as follows:

1. *Search.* In this operation the strobe gate is searched in time until the locally generated interrogation pulse and the received pulse occur at the same time.
2. *Lock.* When a delay time has been found that causes the above-mentioned coincidence, and if this condition persists for about a second, the equipment is made ready to enter the track mode.
3. *Track.* During tracking, the delay is shifted in synchronism with the change of distance between the interrogator and transponder so that distance information is continuously and automatically displayed.
4. *Memory.* If the signal is lost momentarily, the equipment enters the memory phase. Two memory systems may be used, velocity memory or position memory. In velocity memory, the indication is rotated in the same direction and at the same velocity as existed prior to the signal loss. In position memory, the indication remains fixed. If the signal is not recovered in a period of approximately 20 sec, the equipment goes into search operation.

60. Range of Accuracy of DME. Range is dependent upon line-of-sight considerations, the power of the transmitter, the sensitivity of the receiver, and the gains utilized in both the transmitting and receiving antennas. Because of the limitations of available power and weight on the aircraft and the necessity for small antenna sizes, the air-to-ground link generally fails first. From a purely theoretical standpoint, a free-space range of approximately 600 miles is possible with a peak power of 1 kw. The transmissions are limited, however, by normal radio line-of-sight considerations, and the useful range of the civil DME, as used by commercial aircraft, can be considered to be approximately 100 nautical miles.

The factors that produce distance-measuring error can be classified as fundamental or instrumentation. Under fundamental, the most important is the pulse-rise time. With the ICAO system, a pulse-rise time of $\frac{1}{4}$ μsec corresponds to an error of about 0.02 nautical mile. The rise time is of course limited by the allowable band width. A second fundamental error arises from bending or ducting in the atmosphere, but is not a serious factor at 1,000 Mc. A third fundamental error is the variation in the speed of radio propagation.[55] Finally, the large source of error, in so far as navigation is concerned, is that DME measures slant range rather than the geodesic. At high altitudes and close to the station, this error may be very large and, in fact, becomes an altitude indication over the beacon.

The instrumental errors are mainly attributable to the instability of components and the inaccuracies in the generation of frequencies and delays used in the measuring technique. Actual operational errors with existing equipment can be expected to be between 0.1 and 0.25 nautical mile.

61. Arbitrary-course Computers.[56,57] The addition of DME to VOR constitutes a polar-coordinate system where the origin of the coordinates is the location of the station. This type of presentation has the advantage of being the traditional system of geographers and lends itself readily to mechanical position plotting. In addition, this presentation permits the simple computation of arbitrary courses as illustrated in Fig. 36. In the illustration, an aircraft is located at point A at a distance R from a beacon located at S. The bearing of the aircraft from the station (referred to north) is θ. The aircraft desires to fly to an arbitrary destination on a course having a bearing

of ϕ with respect to north. The perpendicular distance from the course to the radio station is D. At all times, the equipment in the aircraft produces indications of R and θ. The arbitrary course is completely described by D and ϕ; therefore the computer is required to solve all values of R and θ that lie on the course. Relatively simple mechanical computers have been developed to perform this function. The results of the computation are presented on the cross-pointer instrument, and the arbitrary course is flown by keeping the instrument centered.

62. Some Avigational Aids for the Short-distance En-route Zone. In addition to VOR and DME, a number of other aids have been employed successfully in short-distance en-route zones. Although not considered for international standardization, these aids serve a useful purpose and, in some cases, are better suited to the specific avigational tasks in those particular areas. This section briefly describes three of
FIG. 36. Diagram of arbitrary-course computation.

these aids; Gee, developed by the British; the visual-aural range developed by the United States CAA; and the v-h-f DF introduced during the Second World War.

During the postwar period numerous new systems for navigation and traffic control were proposed, and a substantial number of these have received some developmental effort. Space does not permit a description of all of these, but a few have been chosen which have undergone considerable development and which incorporate principles that are likely to be used in future developments.

63. Gee. The Gee system was first proposed by R. J. Dippy[58,59] of England in 1937, completed development in approximately 1940, and was used by both British and United States aircraft operating in the European Theater during the war. Although the system was considered, but not accepted, by the Special Radio Technical Division of ICAO, Gee chains have continued to operate in Europe.

Gee is a true hyperbolic system employing synchronous transmission of pulses from three or four ground stations in exactly the same manner as employed by loran. Gee, however, operates at the higher frequencies of 22 to 30 and 40 to 85 Mc. Because the frequencies are quasi-optical, the distance between pairs of a Gee station is 70 to 100 miles. The

pulses transmitted have durations varying from 2 to 10 μsec. The master station of the chain employs a crystal-controlled repetition rate of 500 main pps; however, every other pulse is followed by an auxiliary pulse so that the actual number transmitted is 750 per sec. The second pulse serves as means for identifying the various signals as they appear on the display. The sequence of pulse transmissions is shown in Fig. 37. The first slave station *B* receives the master pulses and after a fixed delay transmits only single pulses at a pulse-repetition rate of 250. The second slave *C* operates in a similar manner and thus incorporates a pulse-repetition rate of 250. The third slave or *D* station transmits a double
FIG. 37. Pulse sequence in a four-station Gee system.

pulse after receiving a single pulse from the master station but has a pulse-repetition frequency of $166\frac{2}{3}$. It can be seen from Fig. 37 that, although the positions of the *B*, *C*, and *D* pulses will change with position of the aircraft, it will always be possible to identify which pulse arrives from which station.

The Gee ground equipment employs techniques which closely parallel those used for loran. Originally, the pulse receivers at the slave stations were connected directly to the Gee transmitter. It was found, however, that fading over the path of propagation between the master and the slave station was sometimes excessive and special circuitry was adopted to overcome this problem. This circuitry involves a stable 150-kc crystal-controlled oscillator at the slave station which is controlled in frequency and phase by the incoming master pulses. The incoming pulses are used to shock-excite a 150-kc crystal filter whose output is compared in a comparator circuit with the output of the crystal-controlled oscillator. Any errors in frequency or phase are used to control a servoamplifier which corrects the crystal oscillator. The oscillator frequency then triggers the transmitter in parallel with the output from the receiver. Accordingly, if the output of the receiver fails from time to time, the required pulses are supplied by the crystal oscillator with no interruption in the transmission.

FIG. 38. Gee display with calibration marks at 150 and 15 kc.

In contrast to loran, stations are not selected by their differences in pulse-repetition rate, but solely by choosing the radio frequency associated with the desired chain.

A typical Gee presentation is shown in Figs. 38 and 39. The measurement technique consists in first identifying the various pulses and then measuring the required time intervals between pulses using accurately controlled time marks. After initial identification using a main time base, a switch is manipulated to change to a strobe time base. The strobe time base is much more rapid and, by adjustment, permits the leading edges of the pulses to be closely aligned. The next step involves the measurement of time difference which utilizes three accurate frequency sources of 150, 15, and 3 kc, respectively. The display then appears as shown in Fig. 38. In this display the marks generated by the 15-kc frequency appear taller than those generated by the 150-kc frequency. The last significant figures of time delay are determined by counting the number of marks between the large mark on the center of the *A* pulse sweep and the large mark on the left of center on the *B* pulse sweep. It is also necessary to estimate the fraction of the scale division to obtain the last significant figure. Next, the main time base (slow sweep) is used to replace the fast sweep and the display than appears as shown in Fig. 39. In this display, the 15- and the 3-kc time sources are used, and by a process similar to that described it is possible to count the divisions corresponding to the first two significant figures of the time delay. In the examples shown in Figs. 38 and 39 the reading is 11.66.
FIG. 39. Gee display with calibration marks of 15 and 3 kc.

The coverage of the Gee system is dependent upon whether two or three slave stations are used. With two slave stations, the area of best performance is limited to approximately 120 deg. To obtain 360-deg coverage, it is necessary to employ a master and three slave stations. At an altitude of 15,000 ft, performance can be expected to a distance of approximately 400 miles from the master station, but at an altitude of 5,000 ft, the range is limited to approximately 300 miles. Assuming that the time difference can be measured with an accuracy of approximately half the distance between the 15-kc marks, an error of approximately ½ μsec results corresponding to a distance of 150 ft. This accuracy can be expected where signal strength is high and the distance is not greater than the length of the base line (70 to 100 miles). At greater distances, accuracy of position fixing is considered to be about ½ per cent of the distance. At maximum range, the error distribution becomes long and narrow and the information received is applicable to determining a line of position rather than a fix.

64. The Visual-Aural Two-course Radio Range (VAR). This system was developed[60] by the CAA beginning in 1939 and constituted an interim navigational aid on the United States civil airways. The device was intended to replace the four-course m-f radio range. In 1941, eight VARs were installed on the Denver–Los Angeles airway. Following the Second World War, the New York-Charleston airway was similarly implemented,[61] but after 1946 it was decided that the omnidirectional radio range was required to provide multiple airways; so no more installations were made. It should be noted, however, that as late as 1951 the two above-mentioned airways were still in operation and provided satisfactory service. Operational experience indicates that the VAR is a satisfactory device where only a single airway is desired.

VAR operates in the 100-Mc band. The space patterns utilized by the device are shown in Fig. 40. These patterns consist of two intersecting lobes, one modulated with 90 cps and the other with 150 cps. The course information is derived by detection and comparison of amplitude of these tones. The relative amplitude is displayed on a zero-center meter which may deflect right or left depending upon which tone is greater in magni-

tude. The course lies at the intersection of the patterns where both tones are equal. This constitutes the visual portion of the range.

In addition to the pair of patterns modulated with 90 and 150 cps, a second, similar pair of patterns is modulated with 1,020 cps keyed in an interlocking Morse-code fashion to produce the characters A and N. The principle employed here is the same as that used for the four-course radio range previously described. Accordingly, an aural course is formed at right angles to the visual course, and is identified as a steady 1,020-cps note. In general, the pilot flies the aircraft by visual reference to the right-left meter and utilizes the aural course only to orient himself with respect to the radio station. In effect, the system provides quadrant identification.
FIG. 40. V-h-f visual two-course range with aural-sector identification.

The transmitting equipment employs techniques which are similar to the localizer of the fixed-beam low-approach system. These techniques are discussed in Part 3. The receiver used with the visual-aural range is the same as that required for the localizer and is also described in Part 3. Briefly, it consists of a crystal-controlled superheterodyne with good AGC. Filters are used to separate the 90- and 150-cps components, which are then compared in magnitude in a bridge-rectifying circuit. The resulting d.c. is applied to a zero-center meter to indicate course location.

The range of the VAR is governed by line-of-sight considerations and can be expected to be approximately 100 miles for commercial aircraft. By flight experience, the optimum course width has been found to be 20 deg, defined as a full-right to full-left deflection.

65. V-h-f Ground Direction Finders. During the Second World War, direction finders (DF) taking bearings on v-h-f transmissions became the primary means of navigation for fighter aircraft. ICAO, however, would not consider these devices as standard aids because of the limited traffic-handling capacity. Nevertheless, their usefulness was realized and, in response to requests from several of its regions, ICAO developed a standardized procedure for use of ground direction finders.[62]

In 1948, Special Committee 31 of the RTCA, which was studying the problem of air-traffic control, recognized the value of v-h-f ground DF and recommended[63] the installation of these units wherever surveillance radar was used. In this application, the DF provides a means of identifying targets on the radar scope. In many areas of the world where traffic densities do not saturate ground direction-finding operations, the device is capable of providing guidance to aircraft which are equipped with a minimum of radio apparatus. In fact, to obtain this service, the only air-borne equipment required is the usual two-way v-h-f communication set.

The principles of operation are discussed in Sec. 31. The antenna system almost universally used for direction finding at very high frequencies is the elevated H Adcock, which has the advantage of low polarization error and large effective height.

The accuracy of a v-h-f DF depends upon the combined effects of instrument errors, polarization errors, and site errors. The inherent instrumental accuracy of automatic DF is kept to an order of about 1.5 deg. Polarization errors on a standard wave may be kept within approximately 4 deg. Site errors are difficult to estimate and vary widely with azimuth. In general, direction finders can be said to have an over-all rms accuracy of better than 6 deg, and under conditions of good siting and accurate calibration, accuracies considerably better than this are possible.

66. The Coordinated-system Concept. The concept of a coordinated system was advanced following the Second World War, particularly for aerial navigation and traffic control, and was accepted as the principle for the ultimate aerial navigation and traffic-control system by Special Committee 31 of the RTCA.[63] The concept provides economies in both the radio spectrum and air-borne equipment. It has been shown by H. Busignies[64] and others that the amount of information required by aerial-navigation systems is small, and the coordinated system concept can be stated briefly

as: "Since the amount of information required to be transmitted for each aerial navigation and traffic function (that is, distance measurement, bearing, instrument approach, etc.) is small, then the most efficient system is one in which all information is carried on a single r-f channel."

The concept is applied practically in the following manner. Every navigation device can be considered to consist of two main parts. The first part is concerned with generating or utilizing an r-f channel, and the second part either impresses navigational information on the channel or extracts it and presents it to a suitable indicator. In conventional systems that have been employed in the past years, each function makes use of a separate group of channels; therefore, it was necessary to employ a separate r-f section (whether it be transmitter or receiver) for each function. The coordinated system can be imagined to be a single transmitting or receiving equipment and all translators, regardless of function, are associated with these two r-f sections.

Shannon[65,66] and others have developed a theory for the information capacity of a channel. The capacity in binary digits, or bits, is given by the expression $C = W \log_2 [(P + N)/N]$.

In this formula, W is the width of the channel in cycles, P is the power of the signal, and N is the power of the noise expressed in the same units as P. For a channel 1 Mc wide and a signal power twice that of the noise power the channel capacity is 1,590,000 bits. White has made the following estimates for the devices employed in short-range navigation, landing, and traffic control:

1. Distance-measuring service: 3,000 bits
2. Beacon identity and altitude: 2,000 bits
3. Azimuth: 48 bits
4. Localizer: 306 bits
5. Glide scope: 306 bits
6. Marker: 50 bits

The total of the above is 5,710 bits. It cannot be presumed that a channel can be used to its maximum theoretical capacity. But since the ratio between the amount of information required and the capacity of the channel is about 28:1, it seems reasonable to assume that a practical system could be evolved.

Another important consideration, however, is the reliability of the coordinated system. It can be assumed that the electron tube is the chief cause of air-borne radio-equipment failure. Assuming a 10-hr flight, the probability of failure of various equipments has been estimated as follows:

1. Distance-measuring equipment: 21 per cent
2. Beacon: 15 per cent
3. V-h-f omnidirectional range receiver: 9 per cent
4. Localizer receiver: 6 per cent
5. Glide-scope receiver: 6 per cent
6. Marker receiver: 3 per cent

If, however, the complete system is important to the fulfillment of a mission, then the reliability of the complete system must be considered rather than the reliability of each individual unit. The total number of electron tubes (neglecting power supply) of the present conventional equipment listed above is 151. In the coordinated system, it is estimated that this number could be reduced to 76. For the conventional system the aggregate probability of failure, for a 10-hr mission, is 45 per cent. For the coordinated system, because of the reduction in the number of tubes, the equivalent probability is 26 per cent. It is thus seen that the reliability of the coordinated system is greater than that of the conventional system taken as a whole but is less reliable than any of the individual units of conventional design. However, because of the savings in the number of tubes of the coordinated system, it is possible to duplicate the system. With duplicate coordinated equipment, the probability of failure is reduced to only 7 per cent.

Accordingly, for approximately the same number of tubes, two coordinated air-borne units may be employed, thus reducing the probability of failure far below that of the conventional system as a whole, and approximately equal to the most reliable component of the conventional system.

The above constitute the main arguments of observers favoring the adoption of a coordinated system of navigation. The following sections describe three systems which utilize these principles at least in part and comprise the Navar Coordinated system, the Sperry Microwave Coordinated system, and the SC-31 system. It should also be noted that Tacan was conceived as a coordinated system, and the compatible addition of ILS service and two-way data transmission has been demonstrated.

67. Navar Coordinated System. Navar is the name coined by the Federal Telecommunication Laboratories for a system of aerial navigation and traffic control on which development started in 1945.[67] As shown in Fig. 41, the Navar system made use of two sets of receivers and transmitters on the ground operating at 3,000 and 1,000 Mc, respectively. The air-borne equipment employs a 3,000-Mc crystal video receiver and a 1,000-Mc transmitter and receiver. With this equipment, the aircraft is furnished with distance measurement, bearing, relayed radar, and traffic-control advice.

On the ground, the 3,000-Mc transmitter and receiver furnish conventional surveillance radar service, and the display incorporates identity-altitude information in the form of numbers. The distance service is furnished in a conventional manner utilizing the 1,000-Mc ground transponder and the 1,000-Mc air-borne interrogator. The details of operation are similar to those already described in Sec. 57 (distance-measuring equipment).

Bearing service is obtained on the 3,000-Mc equipment which utilizes a highly directive rotating beam on the ground. The beam width used is 3 deg. Without interrogation, the 1,000-Mc transmitter on the ground automatically and continuously sends out a distinctively coded set of pulses via its own antenna each time the 3,000-Mc rotating antenna is pointing northward. Since the 1,000-Mc transmission is omnidirectional, all aircraft receive these reference pulses simultaneously. After decoding, the 1,000-Mc reference pulse is used to operate a timing circuit for bearing measurement. The time interval between reception of the reference pulse and the 3,000-Mc radar beam is a function of bearing, this quantity being displayed on an indicator calibrated in degrees from north.

The radar pulse received on the 3,000-Mc receiver serves to trigger the 1,000-Mc transmitter and hence constitutes a beacon reply to the ground. This beacon reply is received on the ground 1,000-Mc receiver and displayed on a conventional radar display except that there are no permanent echoes.

The north pulse received by the 1,000-Mc receiver in the aircraft is used to synchronize the rotation of a deflecting coil on a cathode-ray tube in the aircraft. On the ground, the video output of the radar is used to modulate the 1,000-Mc transmitter. The signals received on the 1,000-Mc air-borne receiver, when applied to the cathode-ray tube, therefore reproduce the ground radar display.

The 1,000-Mc transmissions from the aircraft also convey information to the ground as to the altitude and identity of the aircraft. The altitude is encoded as the spacing between a pair of pulses as governed by an altimeter. The identity is relayed by a special group of pulses arranged in a certain manner by a coding unit. To determine the identity and altitude of an aircraft, it is necessary to operate decoder controls that set a radial and circular cross hair to intersect on the desired target on the beacon-reply display on the ground. This operation decodes the reply, which then appears as a series of numbers on a separate display. With the decoder controls adjusted in the manner just described, it is also possible to send a short discrete message to the aircraft. The elements of the Navar system are shown in Fig. 41.

The Navar system was developed to the point where it was demonstrated as a working unit and was used to prove the practicability of the coordinated-system concept. Many of the techniques used in Navar formed the basis of the Tacan development which followed.

68. Microwave Coordinated System. The Sperry Gyroscope Company has engaged in the development of a coordinated system which is designed to operate at 5,000 Mc and provides bearing-distance service. Because of the difficulty in obtaining very narrow

selectivity in the 5,000-Mc range, the required number of operating channels for a territory with dense air traffic is secured by the use of subcarrier modulations, and the entire system is operated on a c-w basis. With this operation, various services can readily be multiplexed on the same channel by using a different kind of modulation for each service.

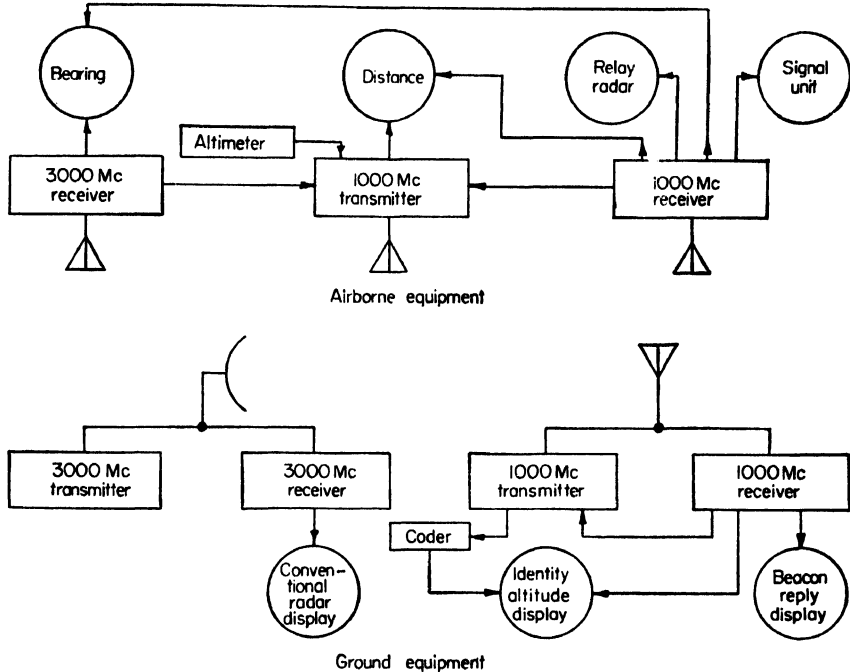
The block diagrams of the system are given in Figs. 42 and 43 for the air-borne and ground equipments, respectively. In the aircraft, the distance measurement is accomplished through the use of two modulating frequencies, namely, 1,000 and 18,600 cps. The signal is received by a microwave receiver on the ground and retransmitted on a different frequency by the transmitter, which is also employed in bearing service. Distance is


FIG. 41. Block diagram of IT&T Navar coordinated system.

derived by phase comparison in the aircraft of the two modulating tones. For example, at a distance of 93 miles, the 1,000-cps transmission relayed by the ground returns to the aircraft at 360 deg out of phase with the transmitted wave. At a distance of 5 miles from the station, the 18,600-cps tone undergoes a similar phase shift of 360 deg. The phase shift of the 18,600-cps tone will, in fact, reproduce every 5 miles and therefore requires the 1,000-cps tone to resolve the ambiguity. The phase detectors associated with the 1,000- and the 18,600-cps frequencies are combined in a selector circuit which controls the rotation of two phase shifters that have suitable gearing between them. This mechanism automatically resolves the ambiguity and displays the information in miles.

The mechanism employed to produce bearing is designed for high accuracy and differs radically from that employed in the VOR. On the ground, a rotating pattern is employed which produces 11 lobes instead of a single rotating limacon. These lobes are received as a sinusoidal modulation in the aircraft receiver and will undergo a phase shift of 360 electrical degrees for approximately every 33 deg of bearing. This vernier effect can theoretically increase the bearing accuracy by a factor of 11; however, there are 11 points of ambiguity that must be resolved. This is accomplished by combining the 11-lobe pattern with a single limacon pattern, the latter selecting which of the eleven 33-deg sectors is the proper one.

The ground antenna is rotated at a speed of 1,650 rpm, which produces a modulation of

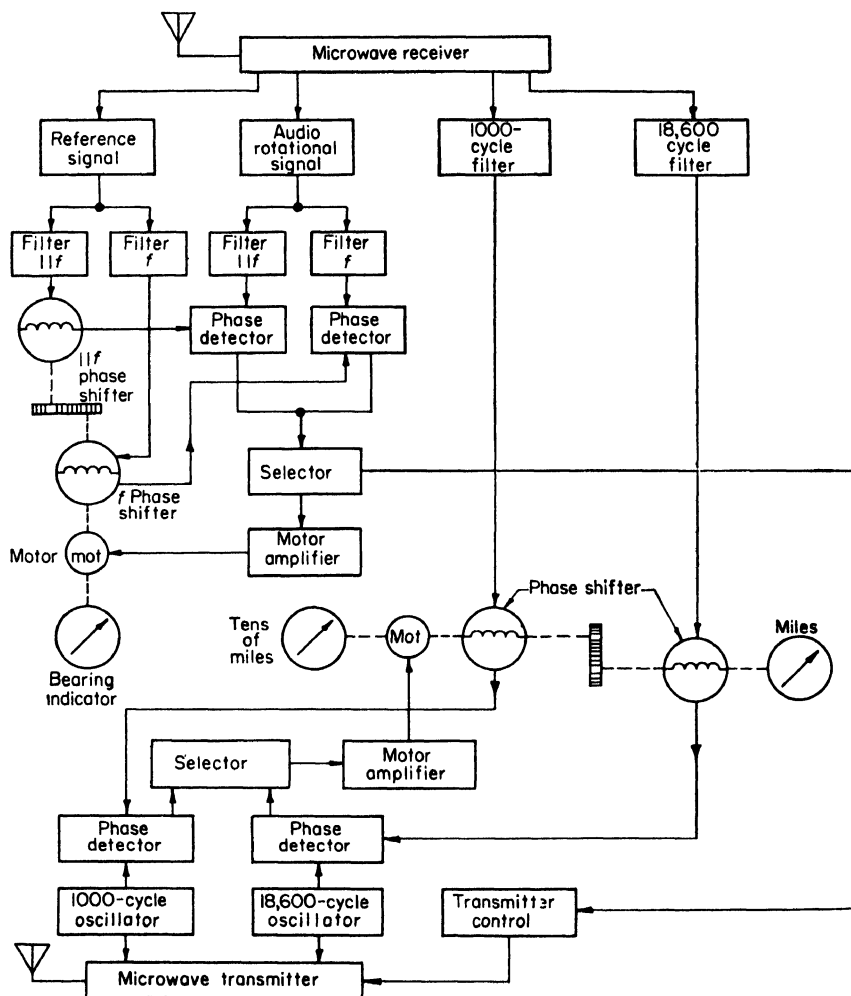
27.5 cps from the limacon and a frequency of 302.5 cps from the 11-lobed pattern. A voltage of 27.5 cps is generated by a permanent-magnet alternator associated with the antenna shaft, and this frequency is used to constitute the reference signal. The reference is impressed on the carrier by a combination of frequency-modulation and subcarrier techniques.


FIG. 42. Block diagram of the air-borne equipment of the Sperry microwave coordinated system.

Azimuth and distance scanning is possible with this system by an arrangement that affords complete position information on the ground corresponding to all aircraft within the area. A separate microwave link is required for this service. The ground transmitter of the link is modulated by a signal which is derived from the reference signal of the omnirange but is caused to vary continuously in phase at a constant rate of, say, 60 deg per sec by passing the omnirange reference signal through a continuously varying phase shifter. This signal is referred to as the variable-phase link signal. On the aircraft, there is already available the variable-phase signal from the omnirange, the phase of which is a direct function of the bearing of the aircraft. A second phase-comparison circuit is provided

on the aircraft which compares the variable-phase signal from the omnirange receiver with the variable-phase link signal.

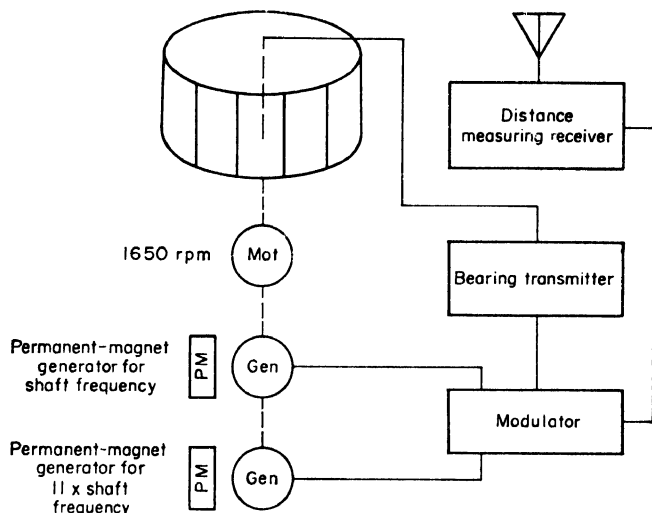
The aircraft transmitter for the separate microwave link is normally in stand-by condition. Its modulation consists of a frequency corresponding to the distance from the ground station and developed in the aircraft as a result of the distance-measuring equipment. As the variable-phase link signal from the ground station passes through phase synchronism with the variable omnirange signal at the aircraft, the output of the second phase-comparison circuit is made to trigger the transmitter. The ground-station receiver then obtains a signal which indicates the distance of the aircraft. The arrangement described also comprises an azimuth-scanning system. Since the signaling phase shifter is varied at a constant rate, the transmissions from aircraft at different azimuth bearings will be separated from each other on a time-sequence basis. The distances of the aircraft will be distinguished from each other on a modulating frequency basis. If two or more aircraft appear at the same azimuth bearing, their transmitters will respond at the same time but will show different modulations according to their distances.


FIG. 43. Block diagram of the ground equipment of the Sperry microwave coordinated system.

The system also permits retransmitting the ground-station information back to the aircraft, thus providing information as to the bearing and distance with respect to the ground station of all aircraft in the area.

A model of the microwave system was constructed and tested to prove the soundness of the principles involved.

69. The SC-31 Coordinated System. Special Committee 31 of RTCA recommended[63] that the coordinated-system principle be applied to a number of equipments in the ultimate system intended to replace the interim common system of aerial navigation and traffic control. Specifically, the committee recommended that the navigational equipment be a transmitter-receiver having multiple channels capable of providing the following services:

1. Distance and bearing information for navigation. These data, when used in conjunction with a computer, should allow the pilot to fly any desired course.
2. Precise slope, localizer, and distance information for instrument approaches.
3. Information for airport-surface navigation to enable the pilot to taxi the aircraft.
4. Air-ground aural communication of a reliable and static-free type.
5. A suitable display in pictorial form that enables the pilot to monitor traffic conditions in his vicinity or receive other pertinent data such as holding areas, air-line locations, and weather maps from the ground.

6. Suitable output to allow the aircraft to be flown automatically either en route or during final approach and landing.

The present state of the art indicates that these ultimate recommendations are attainable, at least to a considerable degree.

70. Tacan. Tactical requirements of the military services prompted the development of the Tacan (tactical air navigation) system. Its background includes the early work on 1,000-Mc equipment (such as Navar) from which its techniques were drawn. These early equipments also included IFF radar and distance-measurement equipment for the armed forces. The main contribution of this early work was the development of 1,000-Mc crystal-control techniques and pulse circuitry which formed the foundation of later equipment.

In 1947, the Navy determined the need to replace its YE/YG beacon, an aural v-h-f navigation system. The Navy undertook tests of existing civil-air-navigation equipment of that time to determine whether any met the requirements, but found that in shipboard use bearing errors were excessive. Accordingly, in 1948, a contract was issued to the Federal Telecommunications Laboratories for the development of a 1,000-Mc omnibearing system suitable for shipboard use. This equipment, designated AN/URN-1 (ground transmitter) and AN/ARN-16 (air-borne receiver), utilized a three-lobe system for bearing information and was suitable for integration with the USAF AN/APN-34 DME. In 1949 a second contract was awarded for integration of the two systems resulting in the AN/URN-3 (XN-1) ground equipment and the AN/ARN-21 (XN-1) air-borne equipment. Contracts were awarded for service-test models of the AN/URN-3 (XN-1) and AN/ARN-21 (XN-1) in 1950. However, these contracts were modified in 1951 to provide service-test models of the equipments to satisfy the joint Air Force and Navy requirements. The main differences between early test models and subsequent production models of AN/URN-3 and AN/ARN-21 equipments were the increase in the number of channels from 50 to 126, the improvement of bearing accuracy by substitution of a nine-lobe system for the three-lobe system, and the increase in range capability to 200 nautical miles.

Fig. 44. Tacan instrumentation providing bearing and distance information from a known reference point.

The Tacan equipment is presently being produced in large quantities for the military forces and has been installed for operational use on many carriers, shore stations, and military air bases. Consideration was given to adoption of Tacan for civil use, and in the fall of 1956, the Air Coordinating Committee recommended the conversion of civil DME to the Tacan channeling. This type of DME, sometimes referred to as DMET, when combined with the civil VOR for bearing, has been termed VORTAC. With VORTAC, any Tacan air-borne equipment can be utilized for civil DME service.

Tacan is a radio aerial-navigation system of the polar-coordinate type illustrated in Fig. 44. That is, there is a *bearing* facility that provides the aircraft with a meter indication of its direction in degrees of bearing from the ground beacon selected by the pilot. Also, there is a *distance* facility that provides the aircraft with a meter indication in nautical miles of its distance from the ground beacon. Knowing bearing and distance from a specific geographic point, the pilot can fix his position on a chart.

71. Principles of Tacan. The radio elements of Tacan are indicated in Fig. 45. The entire system operates in the 960- to 1,215-Mc band. One multichannel air-borne receiver-transmitter, operating with pulses, provides both distance and bearing functions. That is, the same radio signals transmitted over a selected channel convey both distance and bearing information. Actually, both a coarse and a fine indication are combined to produce accurate bearing measurements. Only one air-borne antenna and channel selector are required.

Tacan has 126 two-way operating channels of 1-Mc spacing. For air-to-ground transmission (required only for the distance function), there are 126 frequencies within the band 1,025 to 1,150 Mc. For ground-to-air transmission (serving both bearing and distance functions), there are 63 channels between 962 and 1,024 Mc and a like number from 1,151 to 1,213 Mc. The channels are clear frequencies established solely on the basis of r-f selectivity; they do not depend on pulse coding. Double pulse coding is used to increase the effective radiated power and the signal-to-noise ratio.

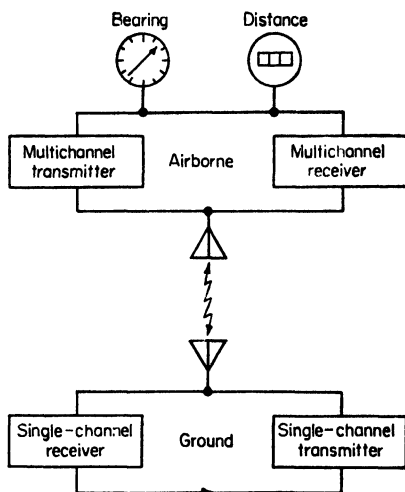
Fig. 45. IT&T Tacan system providing 126 channels for air-to-ground beacon system.

Being conceived as a coordinated system, it is possible to multiplex on the Tacan channels such additional navigational functions as localizer, glide slope, marker, and data transmission. These functions have already been demonstrated experimentally with existing air-borne equipment. When the additional functions are so multiplexed, no further r-f air-borne radio equipment is required. It is only necessary to add adapters and indicators.

72. Tacan Distance Measurement. The principles of distance measurement are identical to those previously described for the civil DME (Sec. 57) but are repeated here to clarify some of the significant differences in channeling and pulse coding.

A given ground beacon may be interrogated simultaneously by a number of aircraft and will reply to all interrogations. Each airplane will receive all the replies being transmitted. To permit interference-free operation under these normal conditions, the interrogation pulses of each airplane occur at a rate that is intentionally permitted to "jitter," or vary within certain limits in an irregular or random manner, by permitting a nonstabilized multivibrator circuit to exercise partial control over the interrogation rate. To sort out those pulses that are replies to its own interrogation pulses, the ranging circuit makes use of an automatic stroboscopic search process.

The strobe locates the reply pulses by finding the one fixed, or very slowly changing, time delay, *always measured from its own previous interrogation pulse,* at which a reply pulse is repeatedly received. Because the interrogation pulses from other aircraft are nonsynchronous or random with respect to those from a given aircraft, reply pulses corresponding to such foreign interrogation pulses will not be received regularly at any fixed time delay on the given aircraft.

The strobe searches automatically each time the air-borne radio set is tuned to a new ground-beacon channel or if there is some *major* interruption in the radio signals. The strobe scans progressively over various time-delay intervals by means of a sliding range gate or time slot. It tests each time-slot position for the number of successive reply pulses received within a certain uniform checking period. If no replies, or only sporadic replies, are received, the strobe advances the range gate to test a slightly longer time-delay interval, and so on. When, at some particular time-delay interval, safe evidence of recurrent replies is detected by a counting process, the strobe has completed its search and stops, since this condition is fulfilled only by reception of the desired reply pulses. Those pulses are the


only ones that are always received in synchronism with the randomly jittered interrogation pulses.

The complete "search" process, covering the entire range of time delays, may require up to a maximum of 20 sec. Thereafter, the strobe locks to the proper reply pulses and converts to a "tracking" operation. Then the delay setting of the range gate automatically and continuously follows any normal variations in the time delay of the proper reply pulses. Such variations occur as the distance between the aircraft and the beacon changes as a result of the flight path.

When the strobe is locked to the proper reply pulses, the time-delay setting of the range gate is a proportionate measure of the distance of the aircraft from the ground beacon (approximately 12 μsec round-trip travel time per nautical mile). The mechanical position of the device that varies the time delay of the range gate is used to control electrically the position of the numerical indicators on the distance meter.

A crystal-controlled 4,044-cps oscillator is used as a time reference. For this frequency, the period $1/f = 242$ μsec, which is the round-trip travel time to an object 20 nautical miles away. In essence, the time interval between interrogation and reply (the time-delay setting of the range gate) is measured in terms of the corresponding number of cycles and fractions of a cycle of the 4,044-cps reference wave.

The time-measuring circuits have a memory provision, so that, if reply signals fail to be received for approximately 10 sec, the existing distance indication will be maintained without the search operation being restarted.

The ground beacon transmits a station-identification signal in International Morse code about every 75 sec and temporarily replaces all reply pulses that would normally occur at that time. The memory feature prevents this substitution from interrupting the air-borne distance indications. On the aircraft, the identification signal is received audibly in telegraphic code.

By strobe principles, which are common to all types of distance-measuring equipment, many (more than 100) aircraft may simultaneously, and without mutual interference, obtain distance service from one ground beacon. Pulse interrogation rates from each aircraft are of the order of 24 per sec during tracking operation; they are temporarily higher, approximately 150 per sec, during the search process. The over-all average rate is considered to be about 30 per sec on the basis that the average aircraft within range will be tracking 95 per cent of the time and searching 5 per cent of the time. The pulses are of the order of 3.2 μsec wide and the duty cycle is very low.

Actually, the pulse signals are always twin pulses, with a prearranged spacing between the two components. The receivers, both ground and air-borne, are followed by twin-pulse decoders that pass only pulse pairs of the prescribed spacing. Isolated single pulses, or pulse pairs with some other spacing, will not pass the decoder. This technique increases the average power radiated and makes the system less susceptible to errors or interference caused by false signals. False signals might be produced by radars, ignition systems, and other extraneous sources, but only rarely will these have the right spacing to pass twin-pulse decoders.

In principle, the transmitter of a distance-measuring ground beacon need not send out pulses except in reply to interrogations actually received. For each such aircraft, it would send out approximately 30 pulses per sec. The total output of the beacon transmitter might then vary from zero to about 3,000 pulses per sec, depending on the existing traffic.

However, one of the major problems with all transponders or beacons is to maintain the receiver sensitivity at the maximum level without having the associated transmitter continually triggered by noise. A very satisfactory solution is to operate the beacon on the constant-duty-cycle principle. In this method of operation, the beacon receiver is provided with an AGC that maintains the number of pulses out of the receiver at an almost constant value, in this case at about 2,700 pulses per sec.

Thus, if few interrogations are being received, the gain of the receiver automatically increases, adding noise-generated "filler" pulses until the requisite total number is obtained. If several more aircraft come within range, the receiver gain drops slightly and the noise-generated filler pulses are replaced by replies to interrogations. If more than 100 aircraft interrogate, replies are made only to the strongest 100 pulses. The relation between gain and number of pulses is such that only a 3-db change in sensitivity occurs between the reception from 1 aircraft and that from 100 aircraft.

An added advantage of this type of operation is the constant current drain on all transmitter circuits. This permits simpler power-supply design, minimizes drifts of tuned circuits, and allows a more predictable component life and maintenance cycle.

Constant-duty-cycle operation has a further advantage. With the beacon always transmitting some 2,700 pulses per sec, there is provided a medium over which other navigational functions can operate. As far as distance information is concerned, it is only the timing of the pulses that matters. Variations in strength of the pulses, produced by pulse-amplitude modulation, may be used to convey additional information. The Tacan bearing function applies this principle.

73. Tacan Bearing Measurement. The heart of any omnidirectional range is the ground-beacon antenna system. It must produce a specified directional radiation pattern that is rotated or switched around a vertical axis. The physical dimensions of an antenna depend on the operating radio frequency or wavelength, and there is a 10:1 reduction in wavelength between the v-h-f band, in which present omnidirectional ranges operate, and the 1,000-Mc region used for Tacan. Advantage is taken of this factor to increase the Tacan-antenna size considerably (in terms of wavelength) for superior performance, while still maintaining reasonably small physical dimensions.

The Tacan ground antenna is fully enclosed in a cylindrically shaped protective cover that is approximately 3½ ft in diameter with a total height, including antenna proper and motor drive, of about 6 ft. No counterpoise is required and the antenna may be installed on a tower or on the mast of a ship.

Figure 46 illustrates the arrangement of the Tacan ground-beacon antenna. Only the central element, shown as a vertical rod, is excited by the transmitter. This is stationary and has no directivity in the horizontal plane. Actually, it is a vertical stack of discone radiators having a diameter of about 3 in.

FIG. 46. Antenna for ground beacon. Central element fixed in position is energized by transmitter. Parasitic elements are embedded in Fiberglas cylinders rotated 15 rps. A reference-pulse disk is mounted on drive shaft below antenna. (*IT&T.*)

Coarse Bearing. Around the central element is an inner cylinder of insulating material (Fiberglas) with a diameter of about 5 in. This cylinder carries a vertical conductive wire that is completely insulated. The wire acts as a parasitic antenna, or reflector, since it intercepts and reradiates some of the energy radiated by the central element. Its distance from the central element is such that it distorts the normal circular radiation pattern into a cardioid, as shown in Fig. 47*A*. The entire cardioid pattern turns 15 times per sec with the rotation of the inner cylinder.

As a result of this rotation, the signal received at any given direction from the beacon goes through corresponding cyclic variations in strength as a function of time. Figure 47*B* is obtained by replotting the polar-coordinate pattern in rectangular coordinates, with time replacing direction angle as the variable of interest. A cardioid thus transformed into rectangular coordinates is simply a sine wave. For this discussion, the unvarying (d-c) component may be neglected. Since the cardioid is a single-lobed pattern, it takes one full turn of the antenna, or ⅕ sec, for the received signal to go through one complete cycle of variation. In short, the airplane receives a 15-cps modulation that may be demodulated into a sine-wave signal.

A suitable reference signal is required for phase measurement. For this purpose, pulse signals transmitted at some fixed phase and at the correct frequency (15 cps) are utilized. These signals are actually transmitted each instant that the maximum of the rotating cardioid pattern aims due east (for a reason to be explained later). These 15-cps, or coarse-reference signals, are distinguished from the distance-measuring signals by their coding. The distance replies or filler pulses are 12-μsec twin pulses that occur irregularly about 2,700 times per sec; hence the interval between these signals is somewhere in the vicinity of 370 μsec. The 15-cycle reference signal, on the other hand, is a precisely regular group consisting of 12 pulses, each a 12-μsec twin, spaced exactly 30 μsec apart.
This reference signal is illustrated in Fig. 47*B* by a group of extra-close pulses and is for a case of an aircraft due south of the beacon. For an aircraft at a different bearing, the time of arrival of these pulses, relative to the maximum of the 15-cycle pulse envelope, would be different from that shown in the figure.

Reference Signal. An aluminum disk attached to the drive shaft of the rotating cylinder of Fig. 46 has a thin iron slug mounted with its periphery in line with the direction of the maximum of the cardioid-pattern lobe. A stationary pickup coil, mounted close to the periphery of the disk, is due east of the center line of the antenna. Hence, once each turn of the antenna cylinder, at the desired standard instant, a signal is inductively generated in the pickup coil to trigger the distance-measuring transmitter into generating the specially coded coarse-reference signal. On the aircraft, this coded signal is separated from the distance-measuring pulses by a special pulse-group decoder and is then used as the timing reference for the measurement of the phase of the pulse envelope wave.
FIG. 47. Circular radiation pattern of central element of antenna is distorted into cardioid pattern at *A* by parasitic element carried by inner cylinder. At *B* the polar-coordinate pattern has been replotted in rectangular coordinates producing a sine wave. The vertical lines represent reply or random pulses, and the group of pulses much closer together are reference signals for phase displacement.

Phase Measurement. In the air-borne receiver, a-f modulation is applied to a calibrated rotary phase shifter, and the output from the shifter is "searched," or moved about in phase, until some preselected index point on the wave is found to coincide in time with the reception of the reference signal. Coincidence is investigated by having a narrow time slot, or gate, formed by the index point on the sine wave, and determining whether the reference signal is received during this time-slot interval. The bearing search may require up to a maximum of 20 sec to complete, depending on the actual bearing at the time. Thereupon the bearing circuits go into track operation. That is, the phase shifter locks to the reference signal and continuously and automatically follows any normal variations in its time of reception with respect to the phase of the bearing-signal envelope. Such normal variations will occur if the bearing is actually changing as a result of the flight path. During the time that the circuits are locked to the reference signal during the tracking operation, the angular position of the rotary phase shifter is a direct measure of the bearing of the airplane with respect to the ground beacon. The angular position of the phase shifter, under proper zero calibration, is used to position the pointer of the bearing meter. This method of operation is stable, accurate, and lends itself to making the bearing data available in the form of a shaft rotation for control of automatic pilots, computers, etc.

The bearing-search process starts automatically each time the air-borne radio set is initially tuned to a new ground-beacon channel or if there is some major interruption in the radio signals. The bearing-measuring circuits also have a memory provision. If, for some reason, bearing signals are lost for a short time up to about 3 sec, the existing bearing indication will be maintained without the search operation being restarted.

All pulses transmitted from the ground beacon, whether intended primarily for distance-measuring reply, filler, station identification, or phase-reference purposes, contribute to forming the a-m pulse envelope or bearing-phase signal. Hence, changing the particular character of the ground-beacon transmissions from time to time in normal system operation does not interrupt or otherwise disturb the bearing-phase signal. Also, radiation of the vital reference signals is arranged to take precedence over any distance-measuring replies, filler pulses, or identity code pulses that might otherwise occur.

The preselected index point actually used for phase measurement is not the maximum of the sine wave, which is a rather broad region, but is the more sharply defined point at which the wave crosses what would be the zero axis in going from its minimum to its maximum value. The index point is ¼ cycle ahead of the maximum, and on the cardioid pattern, it corresponds to a radial index line 90 deg ahead of the maximum. When, in the

course of the rotation of the cardioid pattern, this imaginary index line sweeps past south, the maximum of the cardioid will be momentarily aiming due east. As has been previously stated, the transmission of the 15-cycle reference signal has been standardized to occur at that precise moment.

Bearing Indicators. The bearing meter illustrated in Fig. 44 presents the basic data produced by any omnirange, that is, an absolute bearing or direction angle that is zero-referenced from some fixed geographical direction, generally north (either true or magnetic north, as desired). In line with the type of directional indications that pilots find more directly useful, and to which they are accustomed, the Tacan bearing circuits additionally provide outputs that operate either or both of the standard cockpit indicators, the ID-249 and the ID-250.

On the ID-250 meter, or "radio-magnetic indicator" (Sec. 53), the zero reference is the fore-and-aft axis of the airplane, the top of the fixed meter case (or lubber line) representing the nose of the airplane. To produce this type of indication, the RMI automatically combines Tacan bearing information with magnetic-compass information to actuate the pointer of the instrument. As a result, the angular position of the pointer from the lubber line represents bearing from the aircraft to the beacon measured, not from north, but from the axis of the aircraft. If the meter were to be placed in a horizontal position, the pointer would always physically point toward the beacon, regardless of the heading of the aircraft.
Fig. 48. Antenna pattern (*A*) with single reflector of inner rotary cylinder, (*B*) with nine reflectors of outer cylinder, (*C*) with both inner and outer rotary cylinders.

This relative bearing type of presentation is particularly graphic and convenient for purposes of homing, or keeping the heading of the aircraft aimed directly toward the Tacan omnirange beacon.

On the ID-249, or "course-selector-cross-pointer meter," the center of the fixed meter dial can be considered to represent any selected omnirange radial as the zero reference for the directional indications. This type of presentation is particularly convenient for keeping the aircraft on a given radial track. The pilot sets for a desired radial track by rotating a knob until the selected omnirange bearing figure appears on a numerical indicator. Thereafter, any deviations of the aircraft from the selected radial track are evidenced by sidewise motions of the vertical needle of the cross-pointer meter from the center of the dial. The vertical needle thus directly gives the pilot left-right steering directions for keeping the aircraft on the selected radial. The same principle may be employed for actuating an automatic pilot from Tacan bearing signals.

Fine Bearing. The fine-bearing feature of the Tacan omnirange function produces very greatly improved accuracy over simple cardioid systems. Errors in omnirange bearings arise from two main sources—imperfection of the phase-measuring circuits, which have only some finite limit of accuracy, and, more seriously, radio propagation effects known as site errors. Both errors are significantly reduced by the technique to be described, which requires an increase in antenna dimensions over that for the cardioid or coarse system.

In the case of the Tacan antenna, the necessary increase in size still leaves a compact assembly. Referring to Fig. 46 the inner cylinder has a diameter of about 5 in. The outer cylinder, which is approximately 40 in. in diameter, is constructed of Fiberglas and rotates integrally with the inner cylinder at 15 times per sec. The outer cylinder, however, has 9 wires embedded in it. The wires are spaced uniformly at 40-deg intervals. These wires also are parasitic elements and have a distorting effect on the cardioid pattern produced by the central antenna and inner-cylinder wire. The resulting composite pattern is plotted in polar coordinates in Fig. 48. The over-all cardioid or single-lobed variation is still

present, but superimposed on it are 9 secondary variations or ripples. The maximums of these ripples, or minor lobes, are spaced 40 deg apart.

This envelope signal has a basic $\frac{1}{15}$-sec period, as before, because of the predominant fundamental component due to the rotation of the inner cylinder. The outer cylinder also makes one complete turn in $\frac{1}{15}$ sec, which causes 9 ripples or minor lobes to sweep past the aircraft. Hence the composite envelope wave also contains a ninth-harmonic sine-wave component, having a frequency of $15 \times 9 = 135$ cps. The 135- and 15-cps sine-wave components are separable by filters, and electric phase measurement is performed on each.

To furnish a suitable reference for measuring the phase of the 135-cycle component of the envelope wave, the ground equipment transmits appropriately timed and coded reference
FIG. 49. Block diagram of IT&T Tacan beacon.

signals similar to those for the coarse system. In distinction to both the distance-measuring replies and the coarse-bearing reference signals, the ninth harmonic or fine reference signal is a precisely regular group of 6 pulses, each a 12-μsec twin, spaced exactly 24 μsec apart. In one rotation of the antenna, 8 of these groups are transmitted, separated by 40 deg of rotation. The ninth position is occupied by the 15-cps reference signal.

The important point is that, in the case of the 135-cps signal component, the relation between electric phase and geographic bearing is quite different from that of the 15-cps signal component. Referring to Fig. 48, as an aircraft progresses through a 40-deg arc of bearing, which is the angular width of a minor lobe, the phase of the received 135-cps signal will move through a complete cycle of 360 electrical degrees. Thus, each single degree of bearing change results in a 9-deg change in the measured phase of the 135-cps signal. This ratio of 9 electrical degrees per single space degree gives a pronounced magnifying effect in the process of detecting changes in bearing and forms the basis of the fine-bearing system.

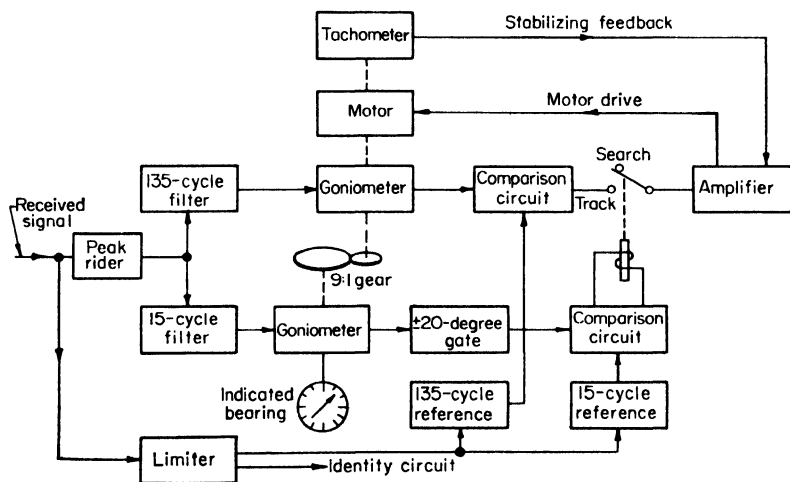
If the bearing indication were given by a pointer that made one dial revolution to indicate 360 deg of bearing, then the circuits should be arranged to produce a 9:1 gearing reduction from the phase measurement to the bearing pointer. One degree of phase shift would then produce $\frac{1}{9}$ deg of pointer movement. If the phase-measuring circuits were accurate to within 1 deg of phase on either side of the correct value, then the bearing-meter indication resulting from measurement on the coarse signal would also be correct to within 1 deg; however, the bearing-meter indication resulting from phase measurement on the fine system would be correct to within $\frac{1}{9}$ deg.
FIG. 50. Air-borne equipment for Tacan.


FIG. 51. Air-borne bearing circuits.

To resolve the ambiguity of the 135-cps phase measurement, the 15-cps phase measurement is used. For convenience and simplicity of interpretation, a conventional 360-deg bearing dial with a single pointer is used. Consequently, the 15-cps coarse phase measurement initially moves the pointer to within the correct 40-deg bearing sector, and thereafter ensures that it remains in the proper sector. The exact positioning of the pointer within that sector is under control of the 135-cps fine phase measurement, suitably geared down. The accurate 135-cps bearing information may also be employed for operation of radiomagnetic indicators, left-right meters, automatic pilots, computers, etc.

The improved site freedom of the Tacan omnirange due to the fine system is one of its most useful attributes. With the present equipments, comparative experimental

tests at various locations have shown very substantial reduction in average and extreme bearing errors caused by site effects, as compared with cardioid systems.

The principal components of the Tacan ground equipment are shown in Fig. 49, and follow the principles described above. The air-borne equipment is illustrated in Fig. 50 with details of the bearing and range circuits shown in Figs. 51 and 52, respectively.

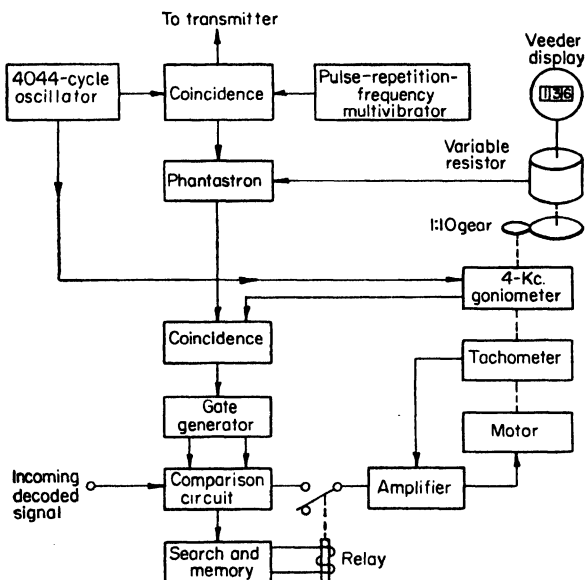
74. Coverage and Accuracy of Tacan. The direct-wave component of the space wave is of principal use; however, reflections from the ground or local obstructions are responsible for site-effect errors and for some lobing of the vertical-plane radiation pattern. Both these effects are reduced by the use of antennas which direct more energy above the horizon than below the horizon. The lobing of the vertical-plane radiation pattern is further reduced by the use of vertically polarized energy and by mounting the antenna a large number of wavelengths above the terrain.


FIG. 52. Tacan range circuit.

At frequencies used for Tacan, coverage and accuracy are not materially affected by factors which usually affect substantially lower frequencies. These factors include electrical ground constants, ionospheric reflections, atmospheric noise, auroral disturbances, precipitation static, etc.

In addition to line-of-sight propagation limitations on coverage, instrumentation circuitry limits the distance-measuring function to a maximum range of 200 nautical miles. The bearing-measuring function has no such limitation; that is, bearing information can be obtained substantially beyond 200 miles when the aircraft is above radio line of sight. With the current standard antenna, bearing information is not available above the ground facility within a total cone of about 90 deg. The angular width of the cone is a function of the antenna design, and new designs are being developed to improve the vertical coverage.

The aggregate bearing error of Tacan equipment currently in service is typically ± 1 to ± 2 deg if the equipment is adjusted so that the mean error is zero. Field tests of modified equipments (both ground and aircraft) have demonstrated the feasibility of errors (excluding attitude-effect errors) within ± 0.5 to ± 1 deg. Future production equipments should be capable of at least this accuracy.

The distance-measuring error of the Tacan system is nominally specified as ±0.2 nautical mile, regardless of range. Modern Tacan equipment operates well within this specification.

Unlike the bearing-measuring accuracy, the distance-measuring accuracy is not appreciably affected by siting or by the reception of a horizontally polarized component.

PART 3

THE EQUIPMENT OF THE APPROACH AND LANDING ZONE

The equipments to be described in this section are those utilized in navigating within the approach and landing zone, *i.e.*, the terminal area. This area has been designated as an airspace of defined dimensions which accommodates aircraft arriving at, departing from, and operating in, the vicinity of airports. It was defined by Special Committee 31 of the RTCA as consisting of the final-approach and live-runway area, the initial approach area, the holding area, and the departure area. The zone[68] is generally considered to consist of a radius of about 30 miles and extending upward from sea level to an altitude of 7,000 ft. These dimensions may vary, and there are reasons to believe[69] that with higher-speed aircraft the altitude may have to be extended. In a large metropolis, several airports forming a single airport system may be located within a common zone.

As in the short-distance zone, the major problem in the terminal area is air-traffic control, but it is more severe in nature since traffic densities are higher. Hence, it is important that the navigational system of the terminal area be capable of producing a controlled safe separation between aircraft that is not wasteful of space and therefore time. With navigational systems utilized in the prewar period, it was necessary to maintain spacings equivalent to 8 min at touch-down. During good weather, however, landings without instruments were made at intervals of less than 30 sec. Attaining safe separations equivalent to this short time interval is the goal of modern electronic navigation systems intended for use in the approach and landing zone. With present operational terminal-area equipment, spacings equivalent to about 2 min have actually been achieved.[70]

Another important distinction of the terminal area is that navigational information must apply in three dimensions. In the two en-route zones, the vertical position of an aircraft is held by reference to a barometric altimeter and navigation information is provided on a two-dimensional basis. In the terminal area, particularly during approach, the altitude must be very carefully controlled if safety is to result.

It is the present philosophy, in air-traffic control for the terminal area, that the burden of maintaining safety rests with personnel stationed on the ground. This provision necessarily requires a large volume of reliable communications and forms a vital part of present traffic-control systems. The communication equipment is covered elsewhere in this handbook, the following section being limited to the electronic aids to aviation.

75. Airport Surveillance Radar. Although radar was first developed for early-warning purposes in the detection of enemy aircraft, it was soon applied to a variety of navigational systems for use with friendly aircraft. The requirements for a surveillance radar were discussed by the Communications Technical Division of the PICAO in 1947,[71] but a firm recommendation for such equipment did not appear until the fourth meeting of the Communications Division held in 1951.[72] When used for air navigation and traffic control, it is essential to distinguish between pure radar systems and those involving interrogators and transponders. Pure radar utilizes only the natural reflection from the target and is termed *primary radar*. The use of a transponder at the target (such as an aircraft) greatly increases the reliability of the "echo," and such a system is called a *secondary* or *cooperative radar*.

Special Committee 31 of RTCA recommended[73] a secondary-radar system for the control of traffic in the ultimate equipment. For the interim period, however, it suggested the implementation of an extensive net of surveillance radar for airport-terminal-area use. It also favored, during this interval, the installation of air-borne beacons that would in effect convert the primary to secondary radars. Such radar installations were made beginning in about 1949, and in the fall of 1950, a meeting was held by the Operational Policy Group of the Air Traffic Control and Navigation Panel of the Air Coordinating Committee in the United States to determine how these equipments could be employed. The recommendation[74] of this group was as follows: "Radar and the radar controller should become the primary means of controlling air traffic at congested terminals. Of all of the aids now becoming available, airport surveillance radar is capable of making the most significant contribution towards increased safety and efficiency of operation. There are a number of sound reasons why the terminal-area traffic-control system should be built around the surveillance radar."

The ACC group also recommended air-borne beacons to cooperate with the ground radar.

Although the operating principles are the same, there are many differences between a ground surveillance radar and air-borne electronic pilotage equipment. The outstanding difference pertains to the source of reflection. With the air-borne equipment, reflection is obtained from an entire area having a diameter of perhaps 100 miles, whereas with the ground equipment the total reflecting surface may be a single aircraft located many miles from the terminal radar. Also, the air-borne equipment requires a maximum range of perhaps 10 miles (the altitude of the aircraft), whereas the ground equipment requires several times this value. The definition must also be improved in ground radars since it is called upon to distinguish safely between two or more closely spaced targets.

The effect of weather on ground radars is more severe than encountered in electronic pilotage equipment because of the normal incidence of propagation with respect to the atmosphere. In air-borne radar, radio waves travel at nearly vertical incidence and are seldom attenuated to a point where they do not yield information on the configuration of the terrain. When used at horizontal angles, the air-borne equipment constitutes a weather radar providing valuable storm information to flight crews. On the other hand, rays from the ground equipment must penetrate this same weather at nearly horizontal angles and be capable of distinguishing a small target.

In the application to traffic control, each target appearing on the screen of a ground radar requires the attention of a controller, and in areas of high traffic density, this requires that the total problem be divided among several persons. Accordingly, it is often necessary to provide a multiplicity of displays.

In general, surveillance radar must utilize high directivity to yield accurate directional information, the p.r.f. must be high to afford indicator persistence, the pulse length must be short for good range resolution, and the peak power must be high to give adequate range. Because of the usual requirement for small antenna structures, the trend is toward the higher frequencies, even though these may exhibit some problems in propagation and high attenuation in certain weather. Surveillance radars operate largely at frequencies in the vicinity of 1,500, 3,000, and 10,000 Mc. A typical example of a primary ground surveillance radar is the search system of GCA equipment, which is described in Sec. 87.

MTI. Primary ground radar, unlike air-borne radar, is limited in close-range operation by permanent echoes caused by terrain features, clouds, or surfaces near the antenna, *i.e., ground clutter.* Since it is desirable to locate a surveillance radar near the airport, it is often not possible to choose sites for best freedom from permanent echoes. A noteworthy contribution to this problem is the moving-target indicator (MTI). The principle employs the Doppler effect, which has been discussed in Sec. 47. Briefly, a simple form of MTI operates in the following manner. The ground transmitter utilizes a master oscillator supplying c.w. and a power amplifier to which the pulsing is applied. The pulsed echoes are then beat with the output of the local mas-

ter oscillator (sometimes called the *coherent oscillator* or *coho*), and the existence of a Doppler frequency indicates that the reflecting object is moving with respect to the radar station. Since permanent echoes result from stationary targets, the beat frequency in these cases will be zero. Hence, by using a high p.r.f. and an appropriate filter, the desired reflection from a moving aircraft can be separated from the undesired reflections or permanent echoes. It should be noted that, if the aircraft is moving at right angles with respect to the line joining the aircraft and the radio station, the beat frequency will be zero and the aircraft will not be seen. Hence, MTI will work only when the rate of closure is not zero. This is characteristic of all MTI circuits.

Displays. Additional displays are often necessary to best utilize the capabilities of a ground surveillance radar. The *plan-position indicator* (PPI) is a popular type of display used in all surveillance radars; however, it has certain weaknesses that are remedied by the use of additional displays. The PPI employs a radial time base with zero time at the center of the cathode-ray display. It constitutes a polar plot with angles measured at the center of the tube representing bearings to various targets that appear on its face. Essentially, therefore, it constitutes a maplike representation. If the scale is not sufficiently large, it may lack the accuracy required by a controller to
FIG. 53. Sector shown at (*a*) for standard PPI display appears as in (*b*) for a *B*-type display.

notice the existence of a dangerous condition or to determine, with sufficient accuracy, what vectors are to be issued to aircraft. Accordingly, two other displays are often used, normally called the *off-center* PPI and the *B display.*

The principles of the off-center plan-position indicator can be visualized by imagining a PPI having a diameter of, say, 12 ft. However, the radar operator has at his disposal an indicator of only 15 or 20 in. in diameter. A control is provided which permits the operator to place the center of the small indicator anywhere he wishes on the face of the large imaginary PPI. The operator, therefore, has available any portion (but not all) of the comprehensive display, with a scale that may be more than ten times the scale of the PPI normally at his disposal.

The off-center plan-position display has its greatest usefulness in increasing the definition of areas located some distance from the radar. However, increased definition is more frequently required near the radar, and for this purpose the *B*-type display offers many advantages. Whereas PPI is a polar-type display, the *B*-type is quasi-rectangular, and the two are compared in Fig. 53. At *a* is shown the face of a cathode-ray tube that might be used for a PPI. The face of the tube is layed out in square areas, and a sector having an angular width of about 60 deg is laid off in dashed lines. The appearance of a *B* display covering approximately the same sector as shown in Fig. 53*a* is shown at 53*b*. The numbered areas in the two displays correspond. The improvement in resolution obtained by the *B* display, particularly in the area that

would correspond to the center of the PPI, is evident. However, directions on the *B* display do not represent bearings as accurately as do those on the PPI.

Height Finding. In some traffic-control applications, it has been found desirable to associate height finding with the surveillance radar. Height finding is employed largely for the purpose of distinguishing between two aircraft in the same area. By communication, the altitude of the aircraft is determined and a height-finding determination is made. This process then serves to identify the target at the altitude corresponding to the communicated information. Height finding is seldom of sufficient importance in surveillance radar to demand elaboration of the basic equipment but is normally accomplished by use of a separate small radar.

The height-finding radar makes use of an antenna that is a paraboloid of elliptical aperture. The antenna is so mounted that its long dimension is vertical. Therefore, it has a narrow pattern in the vertical plane and a broader pattern in the horizontal plane. The antenna oscillates in the vertical plane so that the position of the beam varies from an angle of 2 deg below the horizon to 23 deg above the horizon. This nodding cycle occurs at a rate of about once per second.

Height finders have been constructed to operate at frequencies of 3,000 and 10,000 Mc. The higher frequency is preferred because it is possible to obtain a narrower beam with an antenna of reasonable size.

76. Fixed-beam Low-approach Systems. An instrument low-approach system (ILS) comprises a means for furnishing guidance in the vertical and horizontal planes to aircraft during descent from an initial approach altitude to a point near the ground. Completion of a landing requires guidance to touch-down by means other than the approach system, and when this is provided the combination may be properly termed a landing system.[75] The use of shaped radiation patterns to provide this guidance were first proposed by H. Diamond and F. W. Dunmore[76] of the U.S. Bureau of Standards in about 1928. Early in the Second World War, the United States Air Corps took over the system that the CAA had been developing,[77,78] and produced equipment that was installed throughout the world. The resultant system, developed by the Federal Telephone and Radio Corporation, bore the nomenclature SCS-51.[79] After the war, ICAO adopted the SCS-51 as its standard.[80] In subsequent meetings of the ICAO modifications were made in the original specification but these were largely concerned with more accurate definitions and methods for adjustment of the equipment. Essentially, the basic system originally adopted by that organization has continued to be maintained as a world standard.

A fixed-beam low-approach system consists of three basic components: the *localizer*, the *glide slope*, and *marker beacons*. The approach procedure requires that the aircraft be guided both laterally and vertically, and that some indication of distance be given. Accordingly, the localizer provides lateral guidance, the glide slope provides vertical guidance, and marker beacons are used to indicate the distance to the point of touch-down.

In a standard fixed-beam low-approach system, the localizer transmitter operates between 108 and 112 Mc and is installed at the far end of the runway (opposite from the approach end). It is located so that the center of its antenna array coincides with the center line of the runway. It transmits shaped patterns, to be described later, which essentially define the extended center line of the runway and thereby provide the required lateral guidance.

The glide-slope equipment operates in the 332.6- to 335-Mc band and is located at a distance of approximately 750 ft from the approaching end of the runway and approximately 450 ft to either side of the center line of the runway. This equipment generates a signal which defines a plane inclined with respect to the horizontal and thereby provides guidance in the vertical plane.

The localizer and glide-slope signals are received in the aircraft by means of separate antennas and receivers. The navigational information is displayed on a cross-pointer instrument which incorporates two indicating needles, one pivoted from the top and the other from the side. The position of the vertical needle (which deflects right or

left) indicates the position of the aircraft with respect to the localizer course. Similarly, the position of the horizontal needle (which moves up or down) indicates the position of the aircraft with respect to the glide slope. The aircraft is on the proper approach course when the two needles cross at the center of the instrument.

To indicate progress along the approach path, use is made of three marker beacons normally referred to as the boundary marker, the middle marker, and the outer marker. These markers operate at 75 Mc and are identical with those described previously in Sec. 22. The power of the beacons employed with approach systems is normally of the order of 3 watts. The three markers are distinguished from one another by the utilization of a different modulating frequency. Normally, ILS installations

FIG. 54. Localizer system employing mechanical modulation.

of the CAA in the United States utilize only the outer and middle markers. The boundary marker, if used, is located at a distance of approximately 250 ft from the approach end of the runway, and is modulated at 300 cps. The middle marker, normally located approximately 3,500 ft from the approach end of the runway, is modulated at 1,300 cps. Finally, the outer marker, located at a distance of approximately 4½ miles from the touch-down point, is modulated at 400 cps.

Details of the marker beacon have been previously described; hence the following sections will be limited to a discussion of the localizer and glide-slope components.

77. The Localizer Equipment. A typical standard localizer system is shown diagrammatically in Fig. 54. Some of the systems have used V-type horizontal antennas instead of the Alford loops shown. Arrays have been constructed employing from five to eight loops, but basically the principles remain the same.

The unmodulated transmitter output is connected first to an r-f bridge termed the *cross-modulation bridge.*' The bridge arms are $\lambda/4$ or less in length, and because of the

cross connection at H, the r-f energy from both arms of the bridge arrives at G out of phase and therefore cancels. The adjustment at K is made to balance the bridge, and when so balanced, the bridge serves to divide the total r-f energy into two equal portions and prevent interaction between these portions.

Mechanical Modulator. Modulation has been accomplished by both electronic and mechanical means. Figure 54 employs the mechanical method, which has exhibited a very high order of stability. The mechanical modulator consists simply of $\lambda/4$ transmission-line sections coupled to the lines that lead from the cross-modulation bridge to the antenna bridge. The high-impedance ends of the coupled sections terminate in capacitors. In the center of each capacitor are heavy capacitor plates rotated by a motor. When the coupled sections are tuned, they reflect a virtual short
FIG. 55. Directive field pattern for equisignal localizer (ILS).

circuit in the transmission line. As the rotary plates are engaged, the coupled section is detuned and the short circuit is thus removed. By properly shaping the rotating capacitor plates, it becomes possible to effect a sinusoidal modulation. The mechanical modulator does not add energy and thereby constitutes a downward modulation. With three and five plates, respectively, being rotated at 1,800 rpm, the required 90- and 150-cps modulation components are generated.

Because of the modulation, the input to C on the antenna bridge consists of carrier frequency and side bands of 150 cps. Similarly, at corner B, the input consists of carrier frequency plus side bands of 90 cps. Because of the transposition at D, the carrier frequency will cancel at E, leaving only side bands of 90 and 150 cps. The total carrier energy, plus half the side-band energy, is present at the opposite corner of the bridge and furnishes the excitation for the central antenna of the array. By proper adjustment of cable lengths, the side-band components fed to the side-band antennas are 90 deg out of phase with the corresponding components in the central antenna. A phase reversal is employed at F in the common transmission line joining each set of side-band antennas. Therefore, the side bands on the right-hand side of the array

will be 180 deg out of phase with the corresponding side bands on the left-hand side of the array.

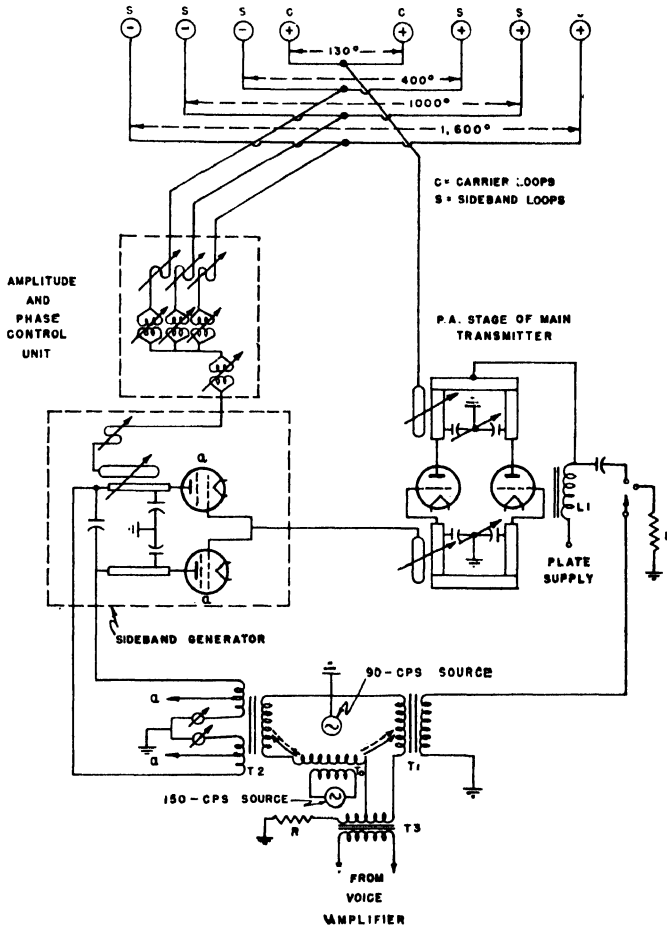
The phasing and distribution discussed above produce directive patterns typified in Fig. 55. Since the side-band energy is symmetrically distributed but out of phase on both sides of the array, these antennas contribute a null along the perpendicular bisector of the array. Hence, along this line, the only energy received by an air-borne


FIG. 56. Localizer system employing electronic modulation.

equipment is that radiated by the central radiator. When the carrier and side-band components of the signal are combined, the resultant modulation field pattern yields virtually 90 cps alone on one side of the runway and 150 cps alone on the other side. The course is defined by the intersection of these patterns, at which point equal magnitudes of 90 and 150 cps are obtained. For this reason, this type of equipment has been termed the *equisignal localizer.*

Electronic Modulator. A typical electronically modulated localizer system is shown in Fig. 56. The principles of operation are generally similar to those described above except that an electronic side-band generator is utilized instead of the mechanical modulator. The side-band generator consists of a balanced modulator in which the

carrier component is canceled in the common plate circuit, leaving only the side-band components. These components are connected to the side-band array as described for the mechanical system. The modulation tones are also applied to the output stage of the main transmitter, which comprises the excitation for the central array. In Fig. 56, two antennas in parallel are utilized for this purpose. Since the equality of 90 and 150 cps determines the course position, it is vital that these two tones be carefully generated and kept balanced in the system.

Two important characteristics of a localizer are the course width and clearance. The course width determines the deflection obtained for a given deviation from the course line. ICAO standards[81] have specified that the localizer must cause a full-scale deflection of the needle when the aircraft has deviated 2.5 deg from the center line. This deflection is a function of the difference between the magnitudes of the 90- and 150-cps components at the output of the radio receiver. Hence, the indicated course width depends upon proper calibration of both the air-borne and ground equipments.

The ratio of amplitude of the two modulation frequencies in any direction, expressed in decibels, is defined as the clearance. Hence the clearance is zero on the course line. For angles up to 2.5 deg on either side of the center line, the meter deflection is very nearly proportional to angular displacement; but for all other angles the deflection should never be less than full scale and should always be in the correct sense. In normal operation, as soon as the needle leaves full-scale deflection, the pilot regards the indication as signifying that the aircraft is within 2.5 deg of the center line and therefore begins to correct the heading accordingly. Hence, should the needle leave full-scale deflection at other regions besides the course region, some confusion may result. Any region beyond 2.5 deg from course in which the needle is not full scale is therefore called a "low clearance region."

One of the most important characteristics of localizer courses is the amount and character of their bends. An excessive amount of certain bends will render a course totally unusable since it becomes impossible to follow it accurately. The bends are caused by reflecting obstacles in the vicinity of the transmitting equipment, and several techniques have been developed for minimizing them. If the obstacles are located generally behind the transmitting equipment, one technique is the use of a reflecting screen which reduces the energy directed at the offending obstacles. In general, however, this technique produces an unflyable back course. A preferred technique is the use of higher directivity and increased sharpness at the intersection of the major lobes. It can be shown that the bending that occurs near the center line of a localizer for a given condition of reflected signal is directly a function of the gain setting of the receiver. However, to retain the same apparent course width, the difference in the side-band field at a given bearing must be increased. This corresponds to saying that the angle of intersection between the two lobes must be decreased so that a given deviation from the on-course position provides a greater difference in the modulation tones. Normally, the generation of a sharper intersection is coincident with more directivity in the lobe structure. Accordingly, less energy is directed in regions remote from the course where reflecting obstacles are more likely to be. This additional sharpness can be obtained by the use of more antenna elements occupying a wider aperture. For this reason, a special localizer equipment designed to produce acceptable courses in poor sites has been termed the "wide-aperture localizer."

78. The Wide-aperture Localizer. Recognizing the need for improved localizer performance, in about 1950 the CAA and the United States Air Force gave consideration[82] to the development of a wide-aperture localizer system, and equipment of this type emerged from production early in 1954. This equipment carries the military nomenclature AN/MRN-7.

The wide-aperture localizer had, as a design goal, a 10:1 improvement in freedom from site effects. The antenna developed for this purpose consists of a screen about 85 ft long and 7 ft high, which mounts 12 horizontal dipoles $\lambda/4$ from its surface. The spacing between centers of all dipoles (except the end elements) is 268 electrical degrees at the central frequency of the localizer band. The last elements are

spaced 308 deg from the centers of their nearest neighbors. All elements, except the two on the extreme ends, are fed carrier energy; hence, an extremely directive carrier pattern results. Side-band energy is fed to all elements of the array with the usual phase reversal between pairs on each side of center. The phase reversal is accomplished by connecting the pairs through transmission-line bridges similar to those previously described. The bridge further serves as a hybrid transformer to isolate the antenna pairs. The r-f inputs are then applied to the two remaining corners of the bridge and permit the simultaneous excitation of the two antennas of the pair with
FIG. 57. Field pattern of a wide-aperture-localizer system.

carrier signal in phase and side-band signal out of phase. Existing transmitters and modulating equipments can be used with this array. One terminal of each bridge (except that for the end element) is connected to terminal A on the bridge shown in Fig. 54. The other terminals of all the bridges are connected to terminal E of the antenna bridge shown in Fig. 54 so that all the antennas are supplied with side-band energy. The bridges are connected to coaxial transmission-line transformers, by which it is possible to match impedances and control the amount of current to the pairs. The resulting side-band pattern of the array is shown in Fig. 57. It is evident by comparison with the normal localizer patterns shown in Fig. 55 that a substantial increase in directivity and pattern sharpness has been attained. Hence, reflecting obstacles to either side of course now receive less side-band energy compared with the

signal in the vicinity of course, and less bends result. To meet the 2.5-deg course-width requirement using a standard localizer receiver, the normal percentage of modulation is adjusted downward so that a standard receiver can fly a normal localizer or the wide-aperture localizer interchangeably.

With the narrow field pattern shown in Fig. 57 it would not be possible to obtain guidance except for a very narrow sector having a total width of approximately 12 deg. To overcome this difficulty, use is made of an auxiliary array employing only three elements. This assembly is called the *clearance array* and its pattern is also shown in Fig. 57. It is located about 50 ft back of the main array and is operated from a separate transmitter having a carrier frequency 10 kc removed from the frequency of the transmitter that excites the main array. The band width of the localizer receiver is such that it readily receives both the clearance- and precision-array signals without retuning. As the aircraft passes from the regions where it receives only clearance signals to the approach position, the signal from the precision array is so much greater that the clearance array no longer contributes to the indication. This phenomenon has been termed "capture" effect and ensures that in the vicinity of course only the precision array is effective.

79. Localizer Apparatus. The ICAO specifies that localizer service over a sector of 20 deg from course shall be provided to a distance of at least 25 nautical miles from the approach end of the runway at an altitude of 2,000 ft. It is also required that, in all other sectors, guidance be provided to a distance of at least 17 nautical miles at an altitude of 2,000 ft. These requirements can be met readily with transmitter powers of from 100 to 200 watts. Actually, the requirements can be met with a radiated power of approximately 25 watts, but if a mechanical modulator is used it must be remembered that its downward modulation does not permit radiation of the total power.

Transmitters have been of conventional design, utilizing crystal control at approximately one-eighteenth of the output frequency, followed by conventional frequency multipliers. Older designs employed balanced circuits because it was believed that balanced excitation of the antenna was necessary to avoid polarization effects. Modern antenna arrays and transmitters, however, have been developed for operation with coaxial lines. Original transmitters, used with mechanical modulators, employed five tubes; but seven tubes (exclusive of audio oscillators and tone generators) are necessary when electronic modulation is employed. Modern transmitters employing coaxial design use only four tubes. Because of the very high gain of wide-aperture arrays, a transmitter radiating 15 watts of power is sufficient for use with this type of antenna system.

ICAO specifies that the localizer shall provide for the simultaneous transmission of an identification signal. It has been the practice in the United States to utilize the identification circuit as an additional ground-to-air communications channel. Tone identification is provided at approximately 1,020 cps. This tone is keyed with a Morse signal by an automatic keyer.

Transmitters employing mechanical modulation have sometimes made use of a separate channel for tone-identification keying. When this technique is employed, an additional r-f bridge is inserted which connects between the antenna bridge of Fig. 57 and the central antenna. The third terminal of the bridge is connected to a modulated r-f amplifier, while the fourth terminal connects to a matching load. It is practical, however, to voice-modulate the main transmitter (which is also mechanically modulated with 90- and 150-cps tones) without employing a separate r-f amplifier. In this case, hum is evident in the voice transmission but the intelligibility has been considered adequate.

During the war years, a radio receiver known as the BC-338 was employed for the reception of localizer signals and provided for six channels. During the postwar period, it was realized that the receiving systems of the localizer and VOR could be conveniently and advantageously combined. Accordingly, receivers produced in the United States for the reception of localizer signals are common with the VOR receiver. Refer to Sec. 50 for remarks concerning this equipment. When the VOR receiver

is tuned to one of the channels designated for localizer operation, the phase-comparison circuit normally used for VOR is automatically replaced with the localizer amplitude-comparison circuit in which the output of the receiver is separated into individual 90- and 150-cps components by filters. The output of each filter then goes to a separate bridge rectifier consisting of a series of copper-oxide elements. These elements are temperature-sensitive, and to prevent the course width from changing as the temperature rises, use is made of a disk-type thermister of high negative temperature coefficient. The outputs of the two rectifiers are then connected in opposition to the localizer instrument. A typical amplitude-comparison circuit is shown in Fig. 58.

As the schematic of Fig. 58 indicates, a voltage is also developed which is proportional to the total of the rectified 90- and 150-cps signals. This voltage is used to actuate a separate coil in the indicating instrument that causes a small tab to disappear from the face of the meter. This tab, commonly called a flag, bears the printed notation "off." Therefore, if insufficient signals are present, the pilot is warned to disregard the indication of the meter. This alarm is vital because, while equal amounts of 90- and 150-cps signals cause the indicator to be centered, the same indication may be obtained if the equipment fails and neither signal is present.
Fig. 58. Circuit for deriving localizer or glide-slope indication.

Errors. There are two main categories of errors attributable to the air-borne receiving equipment, and these consist of the course position and the course width. Initial calibration adjustments are available for both these quantities. With aging, however, some differences in attenuation may occur in the 90- and 150-cps filters, or in the associated copper-oxide rectifiers. The stability of the course width, once adjusted, is mainly dependent upon proper operation of the AGC. To maintain high standards of safety during the critical landing phase, course position and course width are checked at frequent intervals as a normal preventive-maintenance procedure.

Course-position errors are also possible because of distortion of the 90- and 150-cps filters. For this reason, the modulating equipment on the ground and the audio amplifiers in the air-borne equipment are designed for a high order of fidelity.

80. The Glide-slope Equipment. The *equipotential* or *constant-intensity glide slope* attributed to F. H. Dunmore of the U.S. Bureau of Standards plays no part in standard fixed-beam low-approach systems adapted by the ICAO; however, slopes employing this principle were important in all low-approach developments in the years from 1927 to 1941. This type of glide slope, despite several ingenious later modifications, had one or more of the following defects to an undesirable degree.

1. Lack of range or inability to produce a straight-line path more than a few miles in length
2. Lack of uniformity in the glide-slope angle from one airport to another and from one aircraft to another, due to differences in transmitted energies or receiver sensitivities

d. Change of the glide-slope angle depending upon the altitude of the aircraft with respect to the transmitting antenna

81. The Equisignal Glide Slope. These difficulties of the equipotential glide slope are overcome by the equisignal-type glide slope which was first tried in 1938 by D. M. Stewart and J. C. Hromada of CAA. The system, accepted as standard by ICAO, was developed by the Federal Telecommunications Laboratories for the United States Air Force in about 1941.[83] The general principle of operation is similar to the localizer in that overlapping field patterns, carrying different types of modulation, are employed. The position of the slope is therefore determined by the equality of audio tones.

A basic glide-slope system is shown in Fig. 59. The crystal-controlled transmitter operates in the band from 329.3 to 335.0 Mc. The output of the transmitter is handled in a manner completely identical to that of the localizer previously described, except that the antenna bridge is no longer used. Energy modulated at 150 cps is connected to an upper antenna and energy modulated at 90 cps is connected to the lower antenna. Attention is called to the amplitude control whereby the relative amount of energy of the two antennas may be adjusted. For a 2-deg glide angle, the upper antenna is placed at 28.5 ft above ground and the lower antenna at 6 ft above ground. By decreasing these heights while keeping the height ratios constant, the glide angle may be increased to 5 deg in steps of ¼ deg to 4 deg and steps of ½ deg up to 5 deg. With this arrangement, the relationship of the multilobe patterns produced by the two antennas is as shown in Fig. 60. The pattern radiated by the upper antenna has several narrow lobes within the space occupied by the first wide lobe of the lower antenna. Inasmuch as the slope position is determined by the intersection of the upper and lower antenna patterns, only the lowest of the narrow lobes can be permitted to intersect the wider lobe; otherwise multiple courses would be produced. Avoidance of these other intersections is achieved by properly limiting the amplitude of the field from the upper antenna compared with that of the lower antenna. This is accomplished by the amplitude control referred to previously. Too small a signal from the upper antenna, however, results in a somewhat indefinite intersection, as shown in Fig. 60. Even with the intermediate value shown, a false course is produced at the point a', namely, 20 deg above the horizontal. At this high angle, however, there is little chance of confusion since the glide angle is some six to ten times the operationally desirable angle and would be difficult if not impossible to follow.

FIG. 59. Equisignal glide-slope system.

The foregoing analysis has treated the glide slope as though it extended from the region on the ground directly below the two antennas, the equisignal area being in the shape of an inverted cone. Actually, however, the glide-slope equipment is located at a distance of 400 ± 150 ft from the center line of the runway to avoid obstruction to the approach. With this arrangement, the equisignal path along the runway takes the form of a hyperbola, that is, the cross section produced when the cone is cut by a vertical plane other than that passing through its apex. Since the object of the installation is to provide a path which is substantially straight throughout its length, it becomes necessary to counteract the above-mentioned effect. The slope can be changed by adjusting the ratio of the amplitudes of the

field patterns produced by the two antennas. It should be noted that, when viewed from the glide-slope station, the aircraft in its descent subtends a considerable horizontal angle. By employing slightly different directional characteristics in the horizontal plane of the two transmitting antennas, the amplitude ratio between the upper and lower antenna patterns is made to change with horizontal angle from the station by the amount required to produce a straight-line glide slope. The desired effect is obtained by orienting the upper antenna so that its direction of maximum radiation is displaced 12 deg from that of the lower antenna which is parallel with the runway.

The lower antenna consists essentially of half an Alford loop used in conjunction with a reflecting screen, the combination being the equivalent of a full loop except that the transmitted energy decreases rapidly behind the screen. The pattern in front of the screen, however, is nearly circular. The upper antenna is in the form of two V-shaped horizontal dipoles mounted directly above each other at a spacing of λ/2. Both the upper and lower antennas are held by a 3-in. aluminum mast which is mounted on, and guyed to, a small enclosure housing the transmitting equipment.
FIG. 60. Production of an equisignal glide path by intersecting field patterns radiated from two antennas at specified different heights above ground (ILS).

82. The Null-type Glide Slope. At high approach angles, it is necessary for the lower antenna of the equisignal glide slope to be located in close proximity to the ground. Since the patterns are formed by ground reflection, it is easy to understand why heavy snowfall (which reduces the effective height of the antenna above ground) will cause the path angle to change. Recognizing this difficulty, the CAA undertook the development[84] of a null glide-slope system in about 1947. The first equipment embodying this principle was produced under government contract by the Federal Telephone and Radio Corporation as the type TUS glide-slope equipment.

The principle of this equipment is shown in Fig. 61. Similarities can be noted with the equisignal-type system of Fig. 59. The null-type system, however, incorporates an antenna bridge and, in that respect, becomes entirely similar to a typical localizer system. The corner of the antenna bridge which supplies side bands only is connected to the upper antenna while the opposite corner, supplying carrier and side bands, is connected to the lower antenna. There is, in addition, a third antenna connected to the side-band corner, referred to as a "modifier antenna." Its purpose will be discussed later.

The vertical patterns produced by the three antennas are shown in Fig. 62. These patterns indicate that the upper antenna produces a null at the desired glide-slope angle. The patterns have been calculated for an upper antenna height of 4,000 electrical degrees, which corresponds, at 330 Mc, to approximately 33 ft. The two lobes on either side of the glide-slope null contain only side bands, but their phases are in opposition. This phase relation obtains naturally from the ground reflections and can be compared with the phase relation of the right and left side-band antennas of a typical localizer.

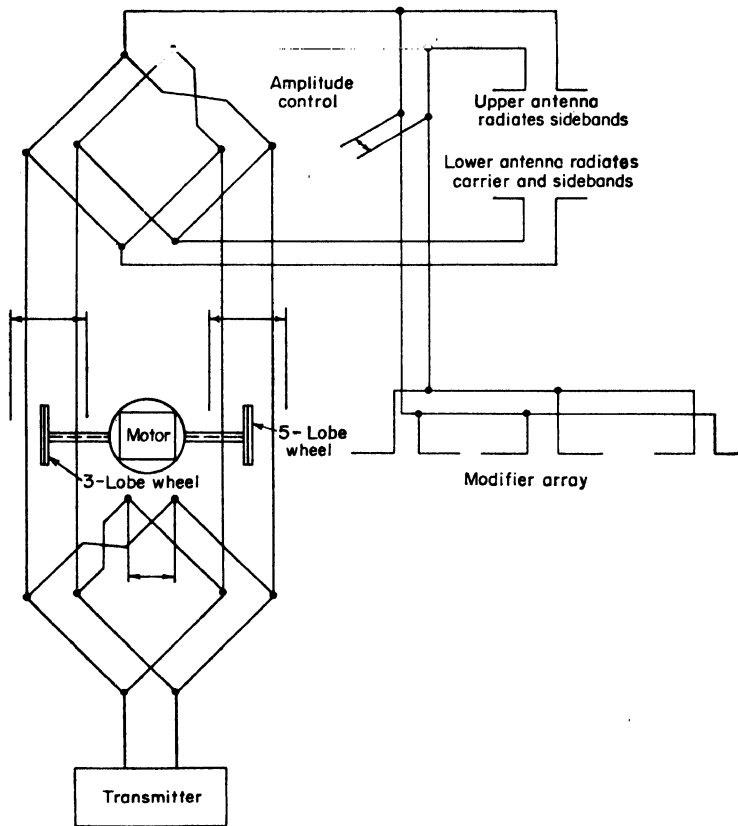
The lower antenna is at exactly half the height of the upper antenna, and as may be seen from the patterns of Fig. 62, its vertical pattern will have a maximum value at the glide-slope position. This antenna, however, radiates carrier as well as the side bands. The 90-cps side-band frequency is in phase with the similar side band in the larger-angle lobe of the upper antenna and is in phase opposition with the similar side band in the smaller lobe of the upper antenna. This condition is reversed for the 150-cps side band. Accordingly, above the glide slope, a preponderance of 90-cps signal exists, while below the glide slope the preponderance is in favor of 150 cps. At the glide-slope angle, there is no contribution from the upper antenna, and since the 90- and 150-cps side bands of the lower


FIG. 61. Null-type glide-slope system.

antenna are equal, the horizontal needle of the cross-pointer instrument will indicate center. If 90 or 150 cps predominates a fly-down or fly-up indication will result, respectively.

The position of the slope in this arrangement is determined only by the position of the null that is generated by the upper antenna. Since the upper radiator is at a height of 33 ft for a 2-deg glide angle, snowfall as high as 2 ft would produce a change in path angle of only 0.13 deg. If the snowfall were as much as 4 ft, the glide slope of the equisignal system would be completely obliterated. However, such a snowfall would cause a change of less than 0.4 deg in the null-type system. It is also evident from the field patterns that the rate of change of indication for about 1.5 deg above and below the course is essentially uniform and leads to a linear deflection of the instrument.

The upper and lower antennas are similar in construction and consist of single dipoles located about $\lambda/4$ in front of reflecting screens.

As discussed for the equisignal-type glide slope, displacing the equipment to the side

of the runway produces a hyperbolic shape at the lower end of the slope. In the equisignal system, a straight-line slope was obtained by altering the relative intensity of the patterns in the horizontal plane. This method is not applicable to the null-type system since the slope position is determined only by the upper antenna. The third or modifier antenna is used for this purpose. The modifier antenna transmits (in the vicinity of the final let-down area or touch-down point) some additional side-band power in such a manner that the existing 90-cps side bands from the other antennas are augmented while the 150-cps signal is decreased. By properly shaping the horizontal pattern of the modifier antenna and controlling its level with respect to the antennas of the main array, the desired straight-line path is accomplished.

83. The Glide-slope Apparatus. Reception of the null-type signal is accomplished with the same glide-slope receiver that is used with the equisignal glide slope, and the ground equipment is so adjusted that it is unnecessary to change any receiver constants in order to fly either system interchangeably.
Fig. 62. Vertical pattern for the three antennas of the null-type glide-slope system.

As in the localizer equipment, it must be borne in mind that the modulation is accomplished through detuning; therefore the maximum power output of the transmitter must be equal to at least the peak power during the modulation cycle. Accordingly, good practice requires that the transmitter power capability be from seven to ten times the nominal carrier output required from the modulator terminals. It has been the practice, in the design of early transmitters, to provide for balanced output systems. Such transmitters employ crystal oscillators operating at about 6 Mc, followed by a series of conventional frequency multipliers to obtain the output frequency of 335 Mc. The final stage consisted of a grounded-grid amplifier and powers as much as 75 watts were obtained.

Modern transmitters employ a coaxial output and are modulated by a bridge modulator also employing coaxial transmission lines. The latter transmitters employ only 5 tubes and 5 adjustments as compared with 8 tubes and 9 adjustments for similar earlier transmitters. The power output of the modern transmitter is in excess of 100 watts.

Many air-borne glide-slope installations presently use a simple horizontal dipole mounted on a vertical standard at a height of about 12 in. above the aircraft fuselage. In one design, the horizontal dipole is mounted on the same vertical standard that supports the localizer antenna referred to as a *ram's horn*. More recently, however, the tendency has been to utilize flush-mounted antennas. These must be mounted in the forward part of the aircraft and have a curved configuration to conform to the shape of the nose of the aircraft. For this reason, although a large number of flush-mounted antennas are on the market, externally mounted antennas may be more popular. One of these antennas has a U shape

that projects horizontally from the nose of the aircraft. The plane of the U is horizontal and its maximum dimension is 5 in. Both ends of the U are terminated in insulating material near the fuselage.

During the Second World War, a glide-slope receiver in common use was the R89, later designated as the AN/ARN-5. These receivers provided reception on three channels in the band from 332.6 to 335.0 Mc. Modern glide-slope equipments provide 20 channels in the band from 329.3 to 335 Mc. A typical receiver weighs approximately 15 lb and utilizes 12 tubes.

One of the operational problems encountered with flying glide slopes is the convergence of the patterns at short distances to the equipment. This convergence causes the path to become extremely sharp and produces undue deflections of the cross-pointer indicator for slight deviations of the aircraft from the slope. The process of eliminating this effect has been termed *course softening*. In early systems, this was accomplished by an additional transmitter operating at the same nominal frequency as the main glide-path transmitter and radiating an unmodulated carrier from a directive array on the same mast. This array was directed toward the runway so that the received magnitude increased as the aircraft approached the touch-down point. The unmodulated carrier desensitized the receiver and thereby reduced the path sharpness as required. In modern systems, however, two general methods are incorporated in the receiver. One method is the application of the gain-control voltage to the audio stages. With such circuitry the relation of output to input may be given any desired shape depending upon the amount of control voltage that is applied to the section of the receiver that follows the detector. Another general method is to utilize an amplified AGC. Some modern receivers use both these methods to obtain the desired degree of course softening.

84. ILS Monitors. ICAO adopted the practice that suitable equipment should be located in the radiation field of the localizer and glide-slope equipments to provide signals for the operation of automatic monitoring equipment. The monitors are required to transmit a warning to a control point and to remove modulation or signal if any of the following conditions arise:

For the Localizer:

1. Shift of the on-course line by more than ⅓ deg from the center line of the runway
2. Reduction of power output to less than 50 per cent of the normal
3. Change of course width of more than 20 per cent

For the Glide Slope:

1. Shift of the path angle by more than 10 per cent of its chosen value
2. Reduction of power output to less than 50 per cent of normal
3. Increase in slope width of more than 10 per cent over the standard value

The above specifications are normally considered to be minimum and monitoring is generally accomplished to somewhat greater accuracies than those specified above.

85. Approach Control Using Heading and Rate. The localizer and glide-slope deflections of an ILS indicate lines of position rather than linear error from the course. At great distances from touch-down, a deflection on the localizer needle requires the pilot to change his heading. Because of the angular nature of the course, however, it will be some time before he crosses the desired course position. On the other hand, when close to the touch-down point, even a small change in heading may cause the aircraft to overshoot. The optimum approach is one which smoothly and asymptotically approaches the course line at any point during the approach. As a minimum, such an approach requires the use of a directional gyro, the bank indicator, and a knowledge of the rate of closure with the course. Circuits have been developed utilizing these factors which solve the problem of an asymptotic approach. One such circuit, developed by the Sperry Gyroscope Company, has been termed the *zero reader*.[85] The information is presented to the pilot on his localizer needle, and in this instance, a centered

needle indicates that the aircraft heading is momentarily correct to make the asymptotic approach rather than the fact that the pilot is centered on the course.

Equipment of this type is employed in automatic pilots for making approaches. In such equipment, the output of the heading-rate-localizer circuit is used to actuate servomechanisms which in turn actuate the aircraft controls. In fact, equipment is commercially available whereby both the localizer and glide-slope signals may be used for complete automatic approaches. This automatic technique[86] has been carried to a point where successful touch-downs have been made experimentally, but it is not yet considered adequate for routine use.

86. Radar Low-approach Systems. A radar low-approach system is intended to supply the same type of information as a fixed-beam low-approach system and the same general definition applies. In April, 1941, personnel assembled by the National Defense Research Council at the Radiation Laboratories associated with the Massachusetts Institute of Technology began to consider means for applying microwaves to the problem of low approaches. Two main goals were to be achieved by this equipment; namely, (1) to circumvent the sensitivity to siting that characterized beam systems developed up to that time, and (2) to make possible the all-weather landing of minimum equipped aircraft (for example, carrying communications only) or aircraft in which the navigational equipment had suffered damage. Flight tests, conducted with an antiaircraft gun laying radar, met with some success and pointed to the modifications required to optimize the equipment for low-visibility approaches. The development that followed led to an equipment called ground-controlled approach, or GCA. The equipment consisted of two radars, one for surveillance and guidance of the aircraft to an optimum approach position, and the other of a more accurate nature for the approach itself. Approximately 200 of these equipments were produced in the United States during the war by three manufacturers and were employed with considerable success by the Armed Services.

At a meeting of a Special Radio Technical Division of the PICAO in the fall of 1947,[87] the GCA equipment was recognized by the statement "that since GCA can perform certain very useful special functions, this system can be employed at those airdromes where local conditions warrant its use as an aid supplementary to the standard system."

The above statement reflected a growing realization by civil air operators of the usefulness of a radar low-approach system as an adjunct to the beam-type system to increase the over-all safety in low-approach operations. This opinion was seconded in the following statement[88] of the RTCA, Special Committee 31, which met between June 12, 1947, and Feb. 17, 1948: "It was agreed that ILS and Precision Beam Radar, when used by aircraft equipped to do so, are complementary and when used together furnish the most dependable landing information." The report included a recommendation for a program to install precision-beam radar equipment at suitable airports where operational requirements justified this action. This decision led to a similar recommendation[89] by the ICAO in its meeting in 1949.

Many airports throughout the world are presently equipped with GCA equipment and, in most instances, the equipment is utilized in support of the beam-type ILS as a very effective monitor and stand-by equipment. There are many instances, however, where the GCA alone has provided successful all-weather approach information.

87. Principles of Radar Low-approach System. GCA consists of two radars termed the *surveillance radar element* (SRE) and the *precision-approach radar* (PAR). The SRE or search system is used for locating all aircraft in the vicinity and directing them to the correct position for landing. The general principles of operation are similar to those described for the surveillance radar in Sec. 75. The SRE component of GCA utilizes a frequency of 3,000 Mc, and the wartime units utilized an r-f peak power of 80 kw. The p.r.f. is 2,000 pulses per sec with a pulse duration of 0.5 μsec. The antenna utilizes a (cosecant)^2 pattern in the vertical plane so as to eliminate a large proportion of ground clutter. The rotation or scan rate is 30 rpm. The PPI display is normally superimposed on a map of the surrounding area so that the operator is able

to tell the exact location of any particular aircraft and, accordingly, can instruct the pilot to avoid obstacles in his path.

Strictly speaking, only the PAR component is used for the low approach. As explained for beam systems, the approach path is defined by the intersection of two planes, which in ILS constitute the localizer and glide slope. A similarity exists in GCA in that two highly directive beams are scanned in the vertical plane and horizontal plane, respectively, and the positional information derived from these defines the course to be followed.

The azimuth antenna (scanning horizontally) utilizes a pattern 0.6 deg wide in azimuth and 1.5 deg wide in elevation. The elevation antenna (scanning vertically) utilizes a pattern 0.4 deg wide in elevation and 3 deg wide in azimuth. The elevation antenna scans 7 deg in the vertical plane while the azimuth antenna scans 20 deg in the horizontal plane. Because of the high directivity required, the antenna apertures must be many wavelengths; hence microwave frequencies (10,000 Mc) are used to keep the antenna structures relatively small. One of the commercial antennas for scanning in the horizontal plane has a length of approximately 8.5 ft and employs 128 dipoles. A typical array for scanning in the vertical plane is approximately 14 ft in length and contains 168 dipoles. Both the azimuth and elevation antennas scan electrically, two to four times per second, by means of a system which mechanically varies the width of the wave guide feeding the transmitting dipole stacks. The mechanism has been termed the *squeezable wave-guide antenna* and was developed by Dr. L. W. Alvarez. Briefly, this mechanism involves the following principle. The dipoles of the array are fed by probes inserted in a common wave guide which runs the length of the array. The individual amplitude is controlled by adjusting the length of the probe, and the initial phase conditions are established by the spacing of the dipoles. By changing the cutoff wavelength of the wave guide, it is possible to change the phase velocity and therefore the relative phase of the excitation delivered to the individual elements of the array. This is accomplished by means of a motor-driven scissors-type mechanism which varies the cross section of the wave guide in the required cyclical manner.

A typical PAR transmitter utilizes a p.r.f. of 2,000 pulses per sec and a pulse duration of 0.5 μsec with a carrier frequency of 10,000 Mc. The energy is applied alternately to the azimuth and elevation antennas by a motor-driven r-f switch. The scanning mechanism is geared to the same shaft and is thus synchronized with the operation of the switch. It further supplies a commutator signal so that the output of the receiver appears alternately on the azimuth and elevation indicators. After careful alignment of the PAR with the runway, the exact position of an aircraft on approach is determined by the beam positions at the instant the echo is received. Since the energy is pulsed, conventional timing techniques are utilized to derive the distance of the aircraft.

88. Instrumentation and Accuracy of the Radar Low-approach System. The effectiveness of the radar approach system is closely associated with the manner in which the data are displayed. During the war, the SRE of the GCA was displayed on a PPI employing range scales of 7.5, 15, and 30 miles. The PAR was displayed on two cathode-ray displays for the elevation and azimuth components, respectively. Each precision indicator utilized two cathode-ray tubes, one covering a 10-mile range (which is the limit of the precision system) and the other a 2-mile range. Typical displays of this type are shown in Fig. 63. To utilize this display, the operators manipulated controls that positioned illuminated lines located on transparent plastic scales so that they were over the spots representing the target. Attached to the scales were cam mechanisms that rotated voltage dividers. The cams were cut with curves that corresponded to the localizer and glide-slope positions that an aircraft should follow in making an optimum approach. With an aircraft making such an approach, the cam positioned the arm on the voltage divider so that the output voltage was zero. A deviation above or below, or to the right or left of the optimum path, produced a corresponding positive or negative output voltage. This voltage was connected to a cross-pointer instrument similar to that used for the ILS beam approach. This instrument was viewed by a third operator who used its indication for calling instructions to the aircraft via the communication equipment.

In civil operations, three operators was considered extravagant, and this requirement led to the development of the presently used display known as the *az-el scope,* on

which there is displayed azimuth, distance, and elevation information. With this equipment, a single operator can call instructions directly from the az-el scope. The display is shown in Fig. 64. Since the azimuth and elevation antennas are alternately excited, the upper, or elevation, display and the lower, or azimuth, display are produced at different times in synchronism with the antenna switching. Both displays are of the expanded type and have their origins near one edge of the cathode-ray screen. For the elevation display, approximately 6 deg of tube surface is equal to 1 deg of elevation, while 3 deg of tube surface is equal to 1 deg in azimuth.
FIG. 63. Information displayed to operators of precision indicators of GCA "talk-down" radar landing system.

Through electronic means, range marks are reproduced on both displays. The total range of the display is 10 miles, but the calibration is nonlinear so that about one-half the display is equal to 3 miles while the remaining half is equal to 7 miles. The range marks incorporate gaps which serve to indicate the direction in which the scanning antennas are pointing. In modern equipment, the operator may adjust the direction of the antenna so that the sweep takes place about this average position. The indication of direction on the scope therefore reminds the operator of the setting of the antennas.

The optimum descent and azimuthal courses are also reproduced on the face of the tube through electronic means. These courses are straight lines in space, but because of the expansion of scales, they appear curved on the face of the display. The circuitry required to produce the az-el display is relatively extensive and includes as its main components antenna-position voltage sources, target-position indicating circuits, chart-generating circuits, cursor-generating circuits, and range-mark generators.

The power output of the transmitter used in the PAR element need not be great because of the high order of gain obtained with the antenna systems. Early designs employ peak powers of only 15 kw, while newer designs have employed powers of 45 kw. Pulses are short, having a duration of approximately 0.2 μsec and rise times of 0.1 μsec.

MTI circuits are employed in some modern equipment, thereby necessitating high pulse-repetition rates of the order of 5,500 per sec. When MTI is not employed, the pulse-repetition rate is normally reduced to about 2,000 per sec.

Modern equipment is capable of resolving targets that are separated by 200 ft in distance, 1.1 deg in azimuth, and 0.6 deg in elevation. At a distance of 1 mile, it is possible to detect deviations from the glide slope of as little as 25 ft. Common twin-engined aircraft can be
FIG. 64. Azimuth-elevation display of postwar low-approach radar.

detected at a distance of about 8 nautical miles. The bearing of an aircraft from the radar can be determined with an accuracy that is equal to 0.6 per cent of the range plus 10 per cent of the deviation from the optimum approach path. In elevation, an aircraft may be detected with an accuracy equal to 0.3 per cent of the range plus 10 per cent of the deviation from the glide slope. Distance to the aircraft may be determined within an accuracy equal to 2 per cent of the distance, provided the aircraft is at a distance of more than 5 per cent of the sweep range in use. The above accuracy figures are based on the assumption that the equipment is operating under conditions of accurate calibration and do not include possible errors due to drift in calibration with time.

89. Landing Altimetry. During the operational use of ILS and GCA equipment during the Second World War, it became evident that no line-of-position guidance system, regardless of its accuracy, was adequate to permit consistently safe landings to the touch-down point in zero visibility. It is not sufficient that the aircraft be

guided to a certain point on the runway, but a landing system must in addition provide a safe rate of descent at the touch-down point and ensure proper orientation of the aircraft. Contrary to electronic systems, during a visual landing the pilot does not attempt to fly a specific path during the last few hundred feet of the landing configuration. If the aircraft is blown to one side or the other (or even vertically) the pilot normally assumes a new path and flare-out condition. The primary concern is the distance above ground, and the rate at which the aircraft is approaching ground. The problem, therefore, subdivides itself into an approach phase and a landing phase. After an approach system similar to those described in Part 3 has brought the aircraft to an accurate position at a height from 50 to 200 ft, a visual or electronic means must be provided whereby the height and rate of descent become accurately known. The electronic means is known as an *absolute altimeter* or *terrain-clearance indicator.*

While the need for supplementing a good approach system with absolute altimetry became evident during the Second World War, the importance of altimetry to air operation was realized as early as 1924 when Alexander Behm[90] invented a sonic altimeter. Other altimeters[91] employing sonic, capacitive, and radio principles were developed in the years from 1924 to 1938. The first quasi-commercial device, however, was produced by the Western Electric Company in 1938 at the request of United Airlines. During the war years, the Radio Corporation of America produced a large number of radio altimeters similar in principle to the Western Electric device and identified as AYB-1 and RC-24. Following the war, many manufacturers entered the field of radio altimetry, and one of the outstanding units, known as the STR-30A, was developed by Standard Telephone and Cables, Limited, London, England.

Operating altimeters have been constructed using the above-mentioned sonic, capacitive, induction, and radio techniques. Although limited success was attained, the sonic, capacitive, and induction techniques are not popular in modern applications and exhibit many practical difficulties. By far the most widely used and commercially successful models are those employing f-m techniques, and accordingly the description that follows is limited to this type.

90. Principles of Frequency-modulated Radio Altimeter. In the pulse altimeter described in Part 1, the minimum distance that can be determined accurately is a function of the duration of the pulse. For example, with a pulse duration of only ¼ μsec the minimum distance would be approximately 250 ft. For landing applications, the accuracy must be considerably better; hence, the pulse-type altimeter is clearly unsuitable for this purpose.

In the f-m altimeter, the frequency of the transmitted wave is varied at some cyclic rate. In the original Western Electric and RCA altimeters, the frequency was varied from its lowest to its highest value in 1/240 sec, but postwar altimeters utilized sweep frequencies of four times this rate.

In operation, a transmitter output is connected to a suitable antenna which directs its energy toward the ground. The energy reflected by the ground is received on a second antenna connected to a radio receiver. The block diagram of a basic system is shown in Fig. 65. Some of the energy from the transmitter is also received by the receiving antenna; hence a beat between the direct and reflected wave appears at the receiver input. The total frequency change between the received and transmitted wave is obviously the rate of change of frequency multiplied by the time required for the transmitted wave to return. Since, as shown in Fig. 66, the rate of change of frequency is maintained constant, the beat frequency will be proportional to the reflection round-trip time. Hence, the beat-note frequency becomes a direct indication of altitude.

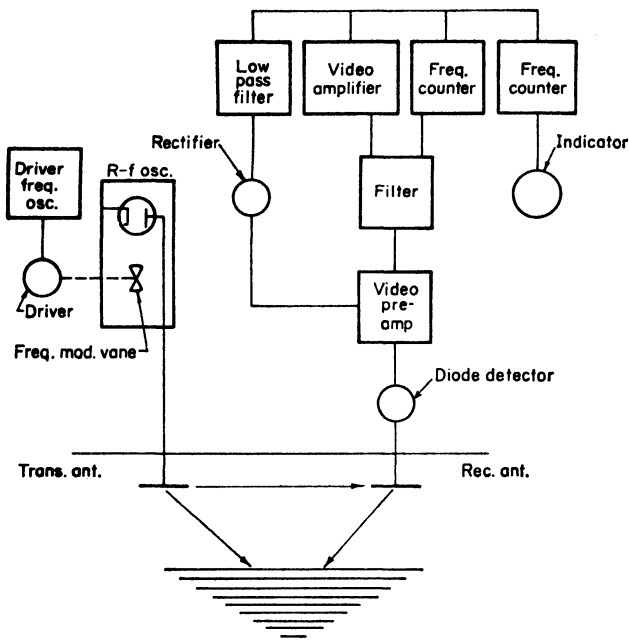
The minimum distance at which frequency may be read is a function of the rate of change of frequency and the frequency deviation. The RCA altimeter, operating at 440 Mc, incorporates a deviation of 40 Mc occurring 120 times per sec. With these parameters, the minimum usable distance becomes 19.5 ft. By utilizing a frequency-measuring system that will read to an accuracy of 10 cycles, distance can be read to approximately ±½ ft.


FIG. 65. Frequency-modulated radio altimeter system.

The Western Electric altimeter operated in the range from 420 to 445 Mc, and the RCA altimeter operated in the range from 420 to 460 Mc. Therefore, the transmitters employed in these equipments were relatively similar. The power output of the Western Electric altimeter was 10 watts, but by the time the RCA altimeter was designed there had been a marked improvement in receiver techniques; therefore, its transmitter was required to produce a power output of only 0.1 watt.

The postwar altimeters have been allocated the band from 4,200 to 4,400 Mc. One of these altimeter transmitters employs a small magnetron while the STC transmitter employs a form of klystron. In the Western Electric altimeter, frequency was varied by a motor-driven capacitor. The STC device followed the same practice. In one American postwar altimeter, as well as in the older RCA device, modulation of the transmitter frequency was accomplished through the use of vibrating reeds located so as to form one side of a capacitor in the oscillator circuit.
FIG. 66. Transmitted and received frequency of radio altimeter together with generated beat note. The beat note disappears at various times during the frequency sweep cycle.

Both the Western Electric and RCA altimeters made use of a form of folded dipole for antennas. The dipoles were about $\lambda/2$ in length, which corresponds to approximately 12 in. The dipoles were horizontal and supported by vertical structures at a distance of about $\lambda/4$ beneath the fuselage of the aircraft. The postwar altimeters

(operating in the 4,000-Mc band) have employed electromagnetic horn antennas. In one American design, the antennas form part of the receiver-transmitter assembly and therefore do not require additional cabling. The horn openings are normally covered with a Fiberglas plate and mount flush with the skin of the aircraft so as to avoid aerodynamic drag.

The indicator circuits of the different altimeters vary in detail. Essentially, however, all consist of a high-gain audio amplifier, an automatic frequency-response control circuit, and a counter circuit. The counter circuit measures cycles per second and indicates the altitude on a meter calibrated in feet. The altimeters from the three major manufacturers are designed to give height to 5,000 ft and include low-altitude scales. As an example, the STC design incorporates a linear scale reading from 0 to 5,000 ft. A second instrument is used for lower altitudes which has an exponential scale so that 0 to 100 ft is indicated in about 135 deg while the remaining 135 deg reads from 100 to 500 ft.

It has been indicated previously that rate of descent is a vital factor in the safe landing of aircraft. In addition, for automatic operation, the second derivative of the altitude (or vertical acceleration) must also be known for proper stabilization of the automatic pilot equipment. For velocity determination, a circuit is used in which a reference pulse samples the received signals, the phase change being converted to a low frequency which is proportional to velocity. This frequency is connected to a counter similar to that used in altitude determination, and furnishes a d-c output proportional to rate of descent or climb. Differentiation of this quantity provides vertical acceleration.

For low-visibility automatic-landing service, the output of the altimeter is combined with the glide-slope signal. Because the rate information increases in importance at the lower altitudes, a circuit is normally employed which deemphasizes the effect of the glide-slope information as the ground is approached. The glide-slope information, on the other hand, swamps out the rate and height information as height increases. The combined information is applied to the horizontal needle of the cross-pointer instrument, which now dictates the optimum landing path rather than merely the location of the glide slope. Systems of this type have been successfully flown experimentally but are not yet considered adequate for routine commercial operation. One of the major problems is the convolutions of the ground in the vicinity of the approach runway. Unless the ground is relatively flat for several hundred feet before the paved runway begins, altimeter aberrations will result during the critical landing phase. This problem is receiving the serious consideration of designers of instrument-landing equipment.

PART 4

THE EQUIPMENT OF THE AIRPORT ZONE (SURFACE DETECTION)

The airport zone has been defined[92] as "that area within the boundary of an airport primarily used for the movement of aircraft and other airport vehicles between various points on the airport excepting (a) the runway or runways currently being used for takeoff and landing of aircraft and (b) localized areas primarily used for the storage and maintenance of aircraft when movement within such areas does not constitute a collision hazard with airport traffic." The importance of the airport zone and its problem was recognized by the Special Radio Technical Division of the PICAO, which, in its meeting of the fall of 1946, expressed itself as follows:[93] "The Division notes the importance of the movement area (airport zone) as being a limiting factor in high density traffic areas. Considerable work has been completed to increase the rate of landing by various means, but the taxiing and dispersal problem has, in comparison, been neglected. The capacity of an airdrome must depend ultimately upon the rate of clearing the runway in use."

91. Requirements. The complexity of taxiways at large modern airports makes it mandatory that control be vested in a central controller who has an over-all view of all vehicles on the airport. When instrument weather prevails, it may not be possible for the controller to observe more than a fraction of the total surface.[94] Accordingly, the following requirements for the airport surface-control system have been formulated:

1. The system must provide a positive indication to the controller of the location of all vehicles on the surface of the airport.
2. The system must be capable of providing the pilot of an aircraft with accurate indication of the route to be followed between the starting point and ultimate destination.
3. The system must permit the selection of any of a series of routes from one point on the airport to another.
4. The system must provide automatic control of traffic and taxiway intersections in such a manner that access to these intersections will be permitted or denied as dictated by collision hazards.
5. The system shall provide safety checks to prevent aircraft collision.
6. The system must report back to the controller the progress which a vehicle has made along the selected path.
7. The system must automatically signal to the controller any dangerous situation arising from the interpretation of control information.
8. The system must provide a means for passing of control from one form to another, that is, from landing control to ground-movement control.

The above requirements indicate that three general types of equipment are needed, as follows:

1. Equipment for determining the position of all vehicles
2. Equipment for providing information as to the identity of all vehicles
3. Equipment for providing guidance instructions

At present, the equipment for item 3 above consists of normal communications gear. However, the advantages of a visual presentation are evident, and serious consideration is being given to this problem. In lieu of item 2, aircraft may be identified through the knowledge of the order in which they are fed into the traffic pattern or from knowledge of their order of departure. Control panels linking traffic to airport control have been devised for this purpose. Item 1 covers a series of devices known as "airport-surface-detection equipment," and these are described in the sections to follow.

As of early 1957, ICAO had not adopted a standard airport-surface-detection (ASD) equipment. In its meeting[95] of 1946, various types were considered, including the pad system with pressure-actuated switches and with light-beam switches, the magnetic-loop system, and the radar system. None of these systems was considered to meet all the desired functional requirements. In recent years, considerable additional work has been done but the actual installation and use of ASD equipment for routine airport surface movement has lagged far behind that for the en-route long- and short-distance zone and the approach and landing zone.

92. Traffic-pad Equipment. The ASD equipment of the traffic-pad type is intended to supply to a controller a miniature display of the entire airport on which there is indicated the position of all vehicles. Traffic pads of an early type were tried at the La Guardia Airport in New York in the years between 1948 and 1950. These were of a simple type incorporating a rubber hose which was placed across the taxiway and which actuated a pressure switch when compressed by a passing vehicle. The switches flashed signals in the tower which were momentary in nature and therefore did not indicate a vehicle stopped between two such paths. Another disadvantage of the system was hindrance to the operation of snow-removal equipment. Proposed systems of a preferred type utilize metal pads level with the surface of the taxiways or detecting devices utilizing the infrared spectrum. Whatever the system for the detection of a passing aircraft, the resulting momentary signals must be associated with other circuits in order to present a continuous display of position.

An example of a proposed block system is one in which the detection equipment is installed in pairs. The distance between elements of the pairs is approximately 40 in.,

with the next pair of elements occurring approximately 150 ft for the length of taxiway to be controlled. Each 150-ft section between pairs then constitutes a movement block. The dimensions given are typical, but any dimensions can be used which experience shows to be desirable. The pairs are connected to relay and indicating circuits which incorporate memory devices such as holding relays or rotary switches. The direction of the vehicle is determined by the sequence of the triggering of the pairs, and the block is released only when the succeeding pairs have been triggered. Circuits are also incorporated for indicating the total number of vehicles that have entered any given block. This provision permits a repair vehicle to enter an occupied block to service an incapacitated aircraft. The information is displayed on a chart showing the occupancy of traffic-movement blocks and the number of vehicles within any block. If it is desired to indicate to the aircraft that the block ahead of it is occupied, a system of traffic lights may be used along the edge of the taxiways.

93. Magnetic-loop System. A magnetic-loop system has been installed and evaluated at the London Airport.[96] This system consists of cables installed in the bitumen joints that provide for expansion between concrete sections. The installation is shown diagrammatically in Fig. 67. In this system, loops of wire are wound around two taxiway sections so that two coplanar coils have a 50 per cent overlap. When excited by an oscillator this arrangement provides essentially zero coupling between adjacent loops.

It should be noted that the pair of coils forms two arms of a bridge circuit, the bridge being completed by additional adjustable elements. The oscillator operates at an audio frequency. Without an aircraft present, the bridge is adjusted for balance and no output results. When an aircraft enters the loop area, coupling between the loops assumes some finite value. In addition, the inductance of the individual loops decreases and the resistance increases. The net effect is an appreciable increase in the potential drop in one arm of the bridge and a decrease in the opposite arm. The result is an output from the bridge (and associated amplifier) which actuates lamps on a chart of the airport. Circuits are also employed to operate lights which are mounted flush with the surface of the taxiway and serve to warn a pilot that the block ahead is occupied.

FIG. 67. Schematic of magnetic-loop system.

94. Airport-surface-detection Radar. An attractive feature of airport-surface-detection radar is its ease of installation. It is recognized that radar serving such a purpose must be capable of very high target resolution; accordingly, development was conducted at wavelengths of 1 cm in England during the late war years and similar work was undertaken in the United States in about 1947 and resulted in a satisfactory test model.[97]

The ASD radar operates at a wavelength of 1.25 cm and has a peak power of 20 kw. Definition is obtained by a relatively large antenna consisting of a horn-fed truncated parabola having a width of 7.5 ft and a height of 3 ft. The antenna produces a field pattern which has a width in the horizontal plane of 0.4 deg measured between half-power points. The pattern in the vertical plane approximates a (cosecant)^2 function and is approximately 10 deg high. The antenna rotates at a speed of between 30 and

60 rpm and is mounted on a tower approximately 30 ft high. Pulse lengths of between 0.015 and 0.08 μsec are available, the most commonly used being 0.02 μsec. The indication is presented on a 12-in. PPI display.

The radar is capable of detecting utility vehicles such as a jeep or fire truck. A typical display is shown in Fig. 68. A twin-engine Douglas DC-3 aircraft is plainly visible on the taxiway. The range accuracy was determined by test to be well under 5 ft. With targets located at a distance of 1,000 ft, it was found possible to resolve two targets when they were separated by 35 ft. At distances of 5,000 ft, it was necessary that the targets be separated by 65 or 70 ft.

A major disadvantage of the ASD radar is that the extremely high frequencies (1 cm) suffer bad propagation attenuations in certain types of precipitation, thereby making the device unreliable even for the short ranges required in this application.
FIG. 68. Display on United States airport-surface-detection radar. Note aircraft. (*Courtesy of CAA.*)

It was found that in light rainfall (0.08 in. per hr) in which the visibility had dropped to less than 1 mile, little effect could be noticed in the operation of the radar. With moderate rainfall (0.25 in. per hr) which produced visibilities of about ½ mile, a Douglas DC-3 could still plainly be discerned on the radar. With rainfall of the order of 0.4 in. per hr, classified as heavy rainfall, the Douglas DC-3 was bearly discernible on the radar.

It was concluded that the ASD radar was satisfactory to provide sufficient information to pilots on runways or wide taxi strips and to provide safe separation between converging aircraft operating on the airport. However, the resolution was not considered adequate for control of aircraft on the terminal ramps or in congested parking areas.

CHAPTER 27

WIRE TELEGRAPHY

By I. S. Coggeshall[1]

The inclusion of chapters on wire communication in a handbook on radio engineering is indicative of the elimination of former boundaries separating wire and wireless, of the identity of much present technique and apparatus, and of the prevalence of end-to-end operation of radio and wire links in "through" telephone and telegraph circuits and services. Radar and the video arts have established radio interest in telegraphic signal elements, pulsing techniques, and codes, and in the extension of their application to industrial automation. The problems of nonlanguage nonredundant information and business data handling and processing serve further to integrate wire and radio telegraphy and telephony.

The fact that the two "wire" chapters (Chaps. 27 and 28) are the last to be added to this handbook accounts for the omission here of expositions commonly appearing in wire-communication texts, or of material already appearing elsewhere in this book, particularly in Chap. 1, the basis of all electrical communication; Chaps. 2 to 5, on circuits of R, L, and C; Chaps. 13 and 14, on electrical measurements; Chap. 17, power-supply systems; Chap. 23, facsimile; and Chap. 24, code transmission and reception in radio. Portions of these, and the other chapters on audio, radio, and electronic circuitry, are basic to modern wire telegraphy and telephony and in certain instances were derived from wire practices and discoveries. Repetition of this included material has been avoided in the wire chapters.

Since engineers whose major concern is specialization in wire telegraphy per se, apart from radio, may already consult texts catering to their purposes,[2] such treatments are not matched here in scope or detail. Omitted also are historical, obsolete, and obsolescent material except where a knowledge of it seems pertinent to new applications or to trends the industry is taking.

Demarcation of the scopes of the two wire chapters, respectively, has necessarily been somewhat arbitrary in view of the fact that the techniques of "record" and "voice" transmission have tended to become unified by their simultaneous occupancy of wire facilities. At one time it would have been possible to say that the use of codes by telegraphy set it apart from telephony, but today speech and music may be encodified during transmission. Telegraphic techniques were once exclusively "narrow-band" compared with telephony; today both appear often as rather similar modulations of megacycle-carrier frequencies. Among the "weak-current" techniques, telegraphy used to employ heavier currents and higher voltages (chiefly d.c.) than telephony, but these are no longer characteristic.

The dividing line adopted, therefore, has been directed to the convenience of the reader. In general, telephony has been made to embrace the *voice band*, 200 to 3,500 cps, and everything above it; telegraphy, the *subvoice* frequencies and the subdividing of the voice band for code. When telegraphic and telephonic modulations, as they often do, ride the same carriers at the same time, the treatment in this handbook will be found under telephony.

[1] The Western Union Telegraph Company, New York.

[2] The principal available texts appear as references at the end of this chapter.

TRANSMISSION THEORY

1. Wire-transmission Objectives. The objective of electrical transmission by wire is the same as that of radio propagation: to create at a distance from a transmitter a disturbance in an electromagnetic field which can be detected by a receiver in such a way that intelligence shall have been conveyed. In both the wire and radio modes of propagation a small portion (milliwatts or microwatts) of the total electrical power sent into the medium of transmission suffices, after local amplification at point of reception or repetition, to actuate the receiver or repeater.

The distinguishing characteristic of wire transmission is its employment of a conductor-dielectric system of continuous material boundaries to guide the energy of the electromagnetic waves rather than to launch it into space. This makes it possible to dispense with r-f waves as carriers of audio and subaudio intelligence modulations, since wire systems transmit energy at all frequencies from their practical upper cutoff frequencies down to zero cps (d.c.).[1]

2. Applicability of Maxwell's Equations. Maxwell's equations (Chap. 1, Sec. 131) are basic to mathematical interpretations of electromagnetic fields in five categories, with which communication theory and engineering are consistent. The first, the *static* case, is unimportant to transmission. The second, the *steady-state* case for stationary (d-c) field, applies, after the passage of an initial wave-front transient, to transmission lines so short, or to frequencies of polarity reversal so low, that the time duration of the shortest impulses employed exceeds the total time of propagation of the transient.

Local-circuit-network theory, based upon lumped linear parameters, typifies Maxwell's (third) *quasi-steady-state* case for closed circuits. So do the "telegraphist's equations" (Sec. 8), applicable to intercity wire transmission lines with distributed parameters, operated at all but the very high frequencies. Thus ordinary a-c network theory may be applied to line problems involving transients, as met with in transmission of telephone carrier over cable pairs, where, because of the higher audio frequencies and relatively slow wave-propagation velocities, sections between repeaters are long enough to span a succession of signal impulses simultaneously, and in transmission over submarine telegraph cables, where despite the low frequencies the same multiple-wave succession exists because of extreme section lengths.[2]

As frequencies are raised[3] past the point (1) where displacement currents are no longer negligible in comparison with conduction and convection currents; (2) where the flow of electrons is no longer streamlined along the conductors but has developed a perpendicular, radiating component;[4] or (3) where, because the dimensions of the circuit exceed about a wavelength of oscillation, the instantaneous electromagnetic field is not uniform throughout—in these events the solutions[5] of Maxwell's equations pass through the (fourth) *quasi-steady* case for open circuits[6] like wave guides[7] into the (fifth) *general* case for dynamic phenomena which includes r-f radiation into space.

Wire transmission and radio propagation are thus seen to be governed by unified physical concepts, with shifting emphasis as the spectrum of frequencies and the circuit electrical parameters and geographical configurations come into play.

3. Propagation of Waves on Wires. Electromagnetic waves on wires may be thought of substantially as though radiated through space but bound to, hence guided by, the "line." A transmission line consists of three essential elements: two conductors of some sort and insulation separating them. Among typical boundary configurations of these three elements may be mentioned: (1) two identical parallel wires of copper, iron, or copper-clad steel, on a pole line, the dielectric being air and glass insulators; (2) a pair of small-gage copper wires in a paper-insulated underground cable; (3) a configuration consisting of one aerial wire on a pole line, the ground or earth constituting the second conductor, and between them air dielectric, wooden poles, and glass insulators; (4) a submarine cable in which a gutta-percha or polyethylene dielectric surrounds one conductor of stranded copper and separates it from a second conductor consisting of steel-armor wires in shunt with sea water; (5) other types of coaxial systems consisting typically of a copper wire within a copper tube, the dielectric being ceramic or plastic supports in air or gas.

Consonant with the two-conductor-and-dielectric concept, applying alike to all these typical line configurations, wire transmission employs, as radio propagation through space also does, familiar features of the kinetic-potential, energy-exchanging, wave-producing mechanism of classical physics. Any increase or decrease in electric-field intensity, propagated outward from a source of disturbance in the circuit, produces a wave front giving rise to variations of magnetic-field intensity; these in turn give rise to further variations of the electric field, and so on. Once established, the original disturbance is sustained by the mutual interaction of electric and magnetic components of the field as the wave travels onward. Free electrons in the conductors are swept into motion (which is another way of saying that the electric charges from the emf source are spread) by the energy exchange taking place as the wave front progresses.

If it is bipolar battery which is applied, it results in the spreading of oppositely poled charges along the respective conductors. The spreading of these opposite positive and negative charges to the far ends of the conductors marks a wave front of instantaneous transient disturbance and initial electron movement at any point, in the directions determined by the polarized fields.

Conduction and convection currents, coinciding with net electron flow in the conductors, are coupled inductively and capacitatively across the dielectric between them to determine circuit constants of propagation velocity, power attenuation, frequency discrimination, and so on, in accordance with circuit theory.

4. Convection of Electrons in Wires. The wave front of electromagnetic-field disturbance, in and about conductors separated by dielectric, is the locus of initiation of the convection of electrons, constituting electric current in the wires. The disturbance may occur at and be propagated almost instantaneously throughout the length of the line from any point on the circuit but in practice usually is associated with a change of polarity or value (including zero, or ground, potential) of applied emf at some point, or with the making or breaking of a charged circuit at any point.

The establishment and maintenance of electron flow is fundamental to the transmission of communication power. The electron stream from cathode to plate in a diode, at velocities of the order of a tenth or more of the speed of light, may properly be thought of as sustained by corresponding flow of the same number of electrons per unit of time through the B battery and the completing circuit of copper wire. But within the copper wire itself, free electrons, which have a net haphazard velocity of about 35 miles per sec at ordinary temperatures, undergo so many atomic collisions that their progressive convection around the circuit under the influence of applied emf is only a fraction of a centimeter per second.[1]

This slow rate of electron progression in a closed circuit might initially seem anomalous with the "lightning" velocities of propagation of wave fronts over transmission lines, varying from, say, 10,000 miles per sec for loaded cable pairs to 180,000 miles per

[1] Morecroft, J. H., "Principles of Radio Communication," 3d ed., p. 12, Wiley, 1933. Darrow, K. K., Electronic Conductors, *Bell Lab. Record*, **33**, 85, 1955.

sec for open wire lines. However, by analogy it will be seen that two consistent independent velocities are involved. If two identical long, taut, parallel horizontal chains were anchored at one end to opposite arms of a lever, and by movement of the lever one chain were suddenly *released* a little and the other simultaneously *pulled* a little more taut, perceptible waves would travel in the same direction along both chains at identical velocities which would be a function of the characteristics of stretched chain and independent of the velocity or direction of the communicated influences, whether they happen to be "pull" or "release."

By analogy and as an electrical transmission-line illustration the wavelength of 1,000-cps a.c. on a 200-mile open-wire pair is 177 miles—indicative that (1) electrons are flowing in opposite directions in the same conductor 88.5 miles apart; (2) in the case of balanced conductors, at any point on the line, including both terminations, the flow of electrons in one conductor is opposite in direction to the flow of electrons in the other; yet (3) the wave-front progression is in a single direction, outward from the point where the source emf is applied, at a velocity of 177,000 miles per sec. It follows that, at the place and instant of application or variation of emf, and in the very process of launching the wave front forward at nearly the speed of light, the electrons in one of the conductors are progressing rather slowly backward into the positive pole of the emf source, somewhat as in the stretched-chain analogy.

The electron-flow concept is also useful in demonstrating the palpable flow of current (at all times and places in a direction opposite to the flow of electrons) once an electron drift has been initiated by the rapid advance of the disturbance front in the electric and magnetic fields along the conductors and the continuation of that drift for so long as the polarity and value of the applied emf remain constant to maintain it.

During such a d-c interval, before a second transient occurs to disturb the fields, there is no further movement in them. In the absence of moving-field interactions there can be no inductive or capacitative effects. Circuit parameters are reduced to series resistance in the conductors and shunt leakage conductance between them. The electron progressions set up by the wave front continue, sustained by the steadily applied emf and in the directions predisposed by the passage of the wave front: forward, out of the battery, into one conductor; backward, into the battery, from the other; and in amounts equal in the two conductors at the emf source. The transmission line, during this interval, obeys Ohm's law for d.c., as Maxwell's special (second) *steady-state* case for stationary fields; it is a circuit for the current but passive as a transmission line, awaiting arrival of a new wave front to alter the direction or volume of drift of electrons throughout both conductors.

5. Uniform Transmission Lines. A line of any constant conformation throughout its length may be thought of as composed of incremental lengths having identical electrical properties. Any convenient unit of length may be chosen, but on long "ground-return" lines it is usual to describe and tabulate the characteristics at a given frequency in terms of their values per mile of geographical distance between the ends and, on metallic-loop lines, in terms of values per loop-mile. The lumped circuit elements are: series resistance R of both conductors, in d-c ohms; inductance L of the conductors in henrys; capacitance C between the conductors, in microfarads; and a leakage resistance, conductance G in micromhos, between the two conductors, as shown in Fig. 1. Where one of the conductors is the ground it is assumed to have a resistance of zero ohms per mile.

Such a line, having uniform characteristics throughout its length, is said to be a "smooth" line, having no impedance discontinuities which would give rise to reflections and consequent power losses. The uniform configuration of the incremental sections gives each one its "characteristic" impedance; matched impedances ensure maximum power transfer from section to section; and if the line is terminated at both ends in matching characteristic impedances, the full transmission value of the line, at any given frequency, is realized.

Although conductors in pairs are usually matched as to material and size, a line otherwise composed (for example, of one copper and one iron conductor or of coaxial

conductors or of one wire and ground) is still a smooth or uniform line if it contains no discontinuities between incremental sections.

Perfectly uniform lines are seldom encountered but in most cases lines are good enough to justify the use of calculations based on formula. Extreme requirements for uniformity sometimes have to be met in engineering—*e.g.*, in ocean-telephone-cable manufacture.[1]

6. Application of Electromotive Force. Signaling emf impressed upon communication wires is ordinarily either applied directly to the two conductors (of whatever conformation, including one wire and ground) or is used to *modulate* (that is, vary the envelope form of) an a-c source in amplitude or frequency. For direct application, the most common form of wave shape is *flat-top* d.c., either interrupted by intervals of zero emf or undergoing polarity reversals, in either case generated commonly by electromagnetically or cam-operated relay contacts, tuning-fork contacts, the sweep of brushes across segmented commutators or faceplates, by hand-operated keys or pole changers, or by circuits containing unidirectional circuit elements such as rectifiers or thyratrons. The flat-top form in certain cases is modified by circuit elements, sometimes for a special purpose such as decreasing the higher-frequency harmonic content to prevent extraneous interference. Sine-wave shapes have upon occasion been used for signaling emf, modulated as to amplitude levels (and hence constituting a carrier system where the carrier and modulating frequencies were identical);[2] but in general the principal use of the sinusoidal wave form of emf is for the to-be-modulated carrier, and the ordinary generator is the tube or transistor oscillator, with or without piezoelectric frequency control.

Any desired wave form may be generated for telegraphic use. In the case of certain submarine cables the sudden discharge of a capacitor into the line produces a peaked sending pulse. Such peaked-pulse forms may be position-modulated for telegraphic as well as telephonic transmission.

In telephony the wave form is generated by electrical coupling with acoustical variations produced by voice or musical instruments. It is treated in accordance with its content of Fourier-series components of sine-wave form.

7. Transient vs. Quasi-steady-state Solutions. When any form of emf is suddenly applied to or removed in whole or in part from a circuit, the upset of the equilibrium of the circuit gives rise to a *transient* the characteristics of which may be calculated by the use of nonperiodic functions, expressed most rigorously in terms of the *Fourier integral*.[3] However, a sufficiently accurate and more convenient engineering approach is commonly made, based upon dynamic equilibrium of a circuit subject to applied a-c emf over a range of frequencies representing the *Fourier-series analysis* of the wave shape important to the transmission; communication-transmission theory is practically founded on such quasi-steady-state relationships.[4]

A complete expression of the effect upon a receiver of emf impressed at the sending end not only has to take into account the transmission losses contributed by the line itself but must consist of the product of additional terms showing the modifications introduced by the sending and receiving apparatus and by reflections from both ends and between ends.[5] Where terminations can be made in the characteristic impedance of the line itself, the reflection factors approach unity. Usually the characteristics of the line are the predominant ones in the calculation of circuit transmission.

8. Applicability of Telegraphist's Equations. For conventional dissipative wire transmission lines including coaxial cables, Maxwell's equations can be converted into accurate forms of "telegraphist's equations" (now more often called *transmission-line*

[1] Kelly, M. J., G. Radley, G. W. Gilman, and R. J. Halsey, A Transatlantic Telephone Cable, *Trans. AIEE*, **74**, Part 1, 124, 1955.

equations) for transmission sections of the form in Fig. 1. It has recently been shown[1] that the equations involving lumped constants of R, L, C, and G are approximately consistent with Maxwell's field theory at much higher frequencies than indicated by their derivation from quasi-steady-state fields and may be generalized in a manner
FIG. 1. Uniform transmission-line pair—1st, 2d, nth miles. For given frequency, lumped circuit constants: series parameters, R, L, $\mathbf{Z}_1$ per loop-mi.; shunt parameters, C, G, $\mathbf{Z}_2$ per mi.; characteristic and matched source and receiver impedances $\mathbf{Z}_0$.

suitable for solving boundary-value problems, thus bringing together theories which have coexisted for many years.

The classical form of the telegraphist's equations for two parallel conductors, each carrying instantaneous current $I_i(z)$ at any point z on the line and separated by a transverse instantaneous voltage of $V_i(z)$ (Fig. 2), is
FIG. 2. Derivation of location (z) functions of instantaneous V_i and I_i values along parallel conductor transmission line having distributed R, L, C, and G computed under static conditions.

$$\frac{dV_i}{dz} = -RI_i - L\frac{dI_i}{dt}$$

and

$$\frac{dI_i}{dz} = -GV_i - C\frac{dV_i}{dt}$$

where R, L, G, C are the distributed values per unit length along the line, computed from static considerations. If sinusoidal I and V are expressed as exponentials, *i.e.*, $I(t) = Ie^{j\omega t}$, $V(t) = Ee^{j\omega t}$, the z functions become

$$\frac{dV}{dz} = -I(R + j\omega L) \qquad \text{and} \qquad \frac{dI}{dz} = -V(G + j\omega C)$$

$$V(z) = ke^{Pz} \qquad \frac{d^2V}{dz^2} = ke^{Pz}P^2$$

$$V(z) = k_1e^{-Pz} + k_2e^{Pz}$$

$$I(z) = \frac{1}{Z_0}(k_1e^{-Pz} - k_2e^{Pz})$$

where k_1 and k_2 are arbitrary constants of second-degree differential equations in V or I.

[1] Schelkunoff, S. A., Conversion of Maxwell's Equations into Generalized Telegraphist's Equations (bibliog.), *Bell System Tech. J.*, **34**, 995, 1955.

From these equations the *propagation constant*[1] (the factor reflecting logarithmic decay of current over each unit length of line) is found to be

$$P = \sqrt{(R + j\omega L)(G + j\omega C)} = A + jB$$

[*cf.* Chap. 5, Eq. (111)], A being the *attenuation constant* (indicating the loss of current magnitude) and B the *wavelength constant* (indicating the increase of phase shift due to time required for energy to traverse unit length of line).

Also, the *characteristic impedance* (sometimes called *iterative* or *surge* impedance) is

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}}$$

Note that the propagation constant and the characteristic impedance disclose product and quotient relationships of the parallel and branched shunt impedances of Fig. 1.

9. Transmission-line Calculations. Tables of transmission-line values are available, recording the results of measurements and calculations based upon standard line-pair configurations at various frequencies from zero to practical upper limits, and for aerial wire line of various pole-pin spacings and for inductively loaded[2] and nonloaded cable. The resistance values go up with frequency, because of *skin effect;* they go down with an increase of conductor cross-sectional size at all frequencies; they rise with ambient temperature and vary with the specific resistance of the conductor material, usually copper, iron, or copper-clad steel. Inductance values go down as frequencies go up and as wire size is increased, and are lower for 8-in. separation on aerial lines than for 12-in. and for the 18-in. pole-pair positions on the crossarms. Capacitance values depend upon contiguity of an aerial pair to other wires on the line and to ground; tables usually specify values for 40-wire lines. Capacitance values are independent of frequency but go up with an increase in wire size and if the line becomes wet. Leakance values, in micromhos per loop-mile, are subject to radical increases with frequency rise and especially with wetting of aerial line, so that the tables contain dry and wet values.

Similar tables for paper-insulated exchange, toll, and spiral-four toll-entrance cable disclose entirely different pair values,[3] as might be assumed from the different structure for aerial wire, but follow similar patterns; effective resistance is affected by proximity of conductors; inductance is low; reactance to temperature variations may be serious and is combated by use of underground cable. Leakage conductance is unaffected by ambient moisture and is further combated by the use of dry gas above atmospheric pressure. Lumped inductive loading of various tabulated types enters the picture to increase the resistance and inductance per loop-mile and produces an upper cutoff frequency not experienced in the case of open-wire or nonloaded cable pairs.

Besides the lumped-circuit constants, the available tables give 1,000-cps values for other calculated and measured line characteristics for aerial wire and toll cable.

An example will show how the values are calculated; and typical cases are shown in Table 1.

1. For 1,000 cps, $\omega = 2\pi f = 6{,}283$.
2. Given R, L, C, and G, $(R + j\omega L)$ and $(G + j\omega C)$ may be calculated, each expressed in polar coordinates in the form of a vector magnitude and an angle.
3. The *characteristic impedance* Z_0 is the square root of the quotient of these respective values, also expressed as a vector and a negative angle. This is convertible to the rectangular coordinates of R and X, in ohms.

Paper-cable example adapted from "Principles of Electricity Applied to Telephone and Telegraph Work," courtesy of Bell System; others, courtesy of A. Boggs, Mrs. C. U. Watts, and C. H. Cramer, Western Union Telegraph Co.

[a] Copper side pair in cable, loading H-44-S; coils M-2, M-3, spaced 1.135 miles, 17.64 coils per wavelength; 4.1 ohms, 0.043 henry per section.

[b] 11.5- or 12-in.-spaced copper aerial conductors in metallic pair, normally transposed; dry.

[c] Nonloaded, armored submarine telegraph cable, simplex operation, single core; 650 lb copper, 375 lb gutta-percha per nautical mile.

[d] Submarine cable (last column only) in nautical miles.

[e] 10 cps in terms of received double bits, equivalent to 20 cps transmitted into cable.

[f] Typical values.

4. The *propagation constant* P is the square root of the product $(R + j\omega L)(G + j\omega C)$ and is expressed as a vector magnitude and a positive angle. The rectangular coordinates are the *attenuation constant* A and the *phase shift* B (in radians per mile)—respectively the cosine and the sine of the angle times the magnitude [*cf.* Chap. 5, Eq. (102)].

5. The total phase shift for the circuit is its loop mileage times the phase constant B per mile, expressed in radians and convertible to degrees.

6. The wavelength of the 1,000-cps wave on the pair is $2\pi/B$ miles.

7. The velocity W of the wave front is $f\lambda$ miles per sec.

8. The line propagation time is $B/2\pi f = 1/W$ sec per mile.

9. To investigate relationships of sent and received voltages, currents, and power losses, one assumes a sending power P_s of, say, 10 mw.[1]

10. The sending voltage E_s will be the square root of 0.01 watt times the magnitude of Z_0 vector over the cosine of its angle (the cosine will be 1 if Z_0 is a pure resistance).

11. The sending current $I_s = E_s/Z_0$.

[1] A numerical example is worked out in "Principles of Electricity Applied to Telephone and Telegraph Work," pp. 161–163, a nonpublished text of the American Telephone and Telegraph Company, 1953.

12. The received current I_r will have been reduced by the action of the shunt paths across each of n sections of line:

$$\log_e \frac{I_r}{I_s} = -nA \qquad \text{or} \qquad 2.303 \log_{10} \frac{I_s}{I_r} = nA$$

from which I_r can be calculated, the other values being known.

13. The magnitude of the received voltage E_r will have been similarly reduced and can be similarly calculated.

14. The received power $P_r = E_r I_r \cos \theta$, where θ is the same angle as in step 10. Voltage and current preserve the same relative phase relationships along the line regardless of the results from step 5.

15. The decibel loss on the line $= 10 \log_{10} (P_r/P_s)$, and the transmission equivalent, or decibel loss, per mile is that amount divided by the length of the line (loop) in miles. The loss expressed in decibels per mile is also obtainable directly by applying a factor of 8.68 to the attenuation constant A (step 4) expressed in nepers. $8.68 \text{ db} = 20 \log_{10} e \text{ db} = 1$ neper.

16. For loaded cable pairs the *cutoff frequency* f_c is approximately $1/(\pi \sqrt{LC})$, where L in henrys is the inductance of the loading coils and C in farads is the total capacitance of the length of circuit between loading coils. Useful range $\leqq 0.75f_c$. Upper practicable design limit $f_c = 30{,}000$ cps. Uniform line equations must be applied to lumped loading conditions with caution.

Table 1 gives values for some selected typical uniform telegraph lines calculated in accordance with the foregoing steps.

Table 2 expresses, for purposes of tentative design of lines of different kinds, exact and approximate noncomplex expressions for A, B, R, and X, derived from the complex equations for P and Z_0.

TRANSMISSION PRACTICE

10. Ideal and Distortionless Transmission. To meet most[1] engineering requirements transmission is acceptable if distortionless, that is, if all frequency components are transmitted without amplitude or phase-shift discrimination. This would be the case if the attenuation were constant at all frequencies and if B increased linearly with frequency. Practical transmission lines, especially in cable, discriminate against the higher-frequency components by attenuating them more and causing them to arrive later than the lower-frequency components. Compensation can be supplied for these discriminations in the receiving amplifier-stage networks by filters which will favor amplification of the necessary higher frequencies and by delay circuits which will hold back the low[2] frequencies until the arrival of the highs. This technique, especially as applied to the critical transmission problems of long submarine cables, is called *shaping*.[3]

Subjective sensations connected with voice transmission make that form of wire communication more difficult to assess against an ideal. Yet telegraphy's demands often prove to be more exacting than its low signaling speeds (say 22.5 to 100 cps) would imply when compared with a voice mid-band frequency of 1,000 cps; for voice-frequency content in the vicinity of, say, 3,000 cps might be attenuated yet the circuit remain commercially acceptable, whereas the same frequency discrimination in a voice band assigned to telegraphy might render a portion of the spectrum below 3,000 cps useless. A telephone plant consisting of a variety of loaded, nonloaded, and carrier circuits of differing characteristics will transmit speech (200 to 3,500 cps) without impairment; yet the transmission of high-speed [750 bits per second (bps)] digital information (such as signals, data, switching, ringing, telegraphs) will be affected[4] unless confined to the portion of a (voice-frequency) band lying between 700 and 1,700 cps.

Ideal or *perfect transmission* has two additional attributes beyond that of being distortionless: no loss of energy (zero attenuation constant A) and no time displacement or propagation time (zero phase constant B). The first requirement has lost its importance, except for critical relationships of received power to received noise, ever since amplifiers have made it possible to compensate for all power losses on lines and in apparatus. Low propagation time assumes importance in certain duplexed applications: in telephony, in permitting speakers at circuit ends to conduct conversation naturally (Chap. 28, Sec. 32); and in modern forms of telegraphy, in providing for the automatic correction of transmission errors revealed by *error-checking* devices (absolute delay; see Chap. 24, Sec. 71).

Ideal transmission also is not interfered with by external disturbance, nor does it introduce disturbance into other circuits.

Telegraph engineers customarily apply other criteria than transmission accuracy in judging a circuit to meet the "ideal": (1) its total attenuation (that is, its received-signal level) should be such that with standard amplifying repeater equipment it can be joined, end-on, to other sections of line to make up circuits of any required length; (2) it must not have made extraordinary demands as to repeater spacing (in miles); (3) its transmission band should be of such width as to accommodate a standard number of channels without quality deterioration at frequency extremes; (4) its electrical influence must not be felt in adjoining circuits or by radio transmission from its wires or telegraph instruments (Sec. 17).

11. Arrival Curves. Expositions are contained in Chap. 1 on the subjects of harmonic functions, the frequency spectra of square-top (rectangular) and sine-wave forms, and the application of Fourier analysis and coefficients to complex wave forms, all as applied to distortionless transmission. In the use of modern carrier techniques the usual received wave shape is that of complex sine-wave modulations (either a-m or f-m) of an a-c carrier; however, the nature of an arrival curve (the plot of received voltage, current, or power vs. time) and the mechanism for shaping it are most easily understood if the given applied sending emf is rectangular.

The perpendicular (abrupt) transition from *space* (S) to *mark* (M) or from mark to space conditions (the effect is the same) contains all frequencies from zero to infinity; and it determines the arrival curve which, but for the frequency nonlinearity of the attenuation A and phase-shift B components of the propagation constant, would also be perpendicular. But if, as customary, the higher frequencies are attenuated or delayed in transmission, the tendency is to round off the corners of the wave in a definite manner, so that a more or less rounded signal is the result. Such rounding off is not objectionable if not carried too far. Since the higher frequencies are the most difficult to transmit, the ideal curve is one which, while giving acceptable signals for the type of telegraph system being used, requires the transmission of the smallest possible amount of the higher frequencies.

The Fourier series for the rectangular perpendicular curve shows the diminishing importance of harmonics of a transmitted frequency beyond the fifth in building up a simulation of the rectangular shape or, what is the same thing, in specifying the amplitude-frequency spectrum of the received wave form. However, in wire-telegraph transmission, even that involving f-m carrier, the required band width is only 2.3 times the fundamental signaling frequency;[1] and in the critical operations of ocean cables it may be as little as $1.65f$ for operating relays.[2]

The arrival curve of an abrupt space-mark sending transition is shown in Fig. 3. The system is determined experimentally or by design[3] to be capable of transmitting frequencies from zero to $\omega_0 = 2\pi f_0$.

$$E_r = E_s e^{-A_0} \cdot f(t)$$

$$f(t) = \frac{1}{2} + \frac{1}{\pi} \int_0^{\omega_0} \frac{\sin \omega t}{\omega} \, d\omega, \text{ which is the function plotted in Fig. 3}$$

Time t, which, as noted above, occurs $B/2\pi f$ sec after application of E_s, marks the beginning of the wave-front slope. The *interval of effective rise* of current $T = \pi/\omega_0 = 1/(2f_0)$. The *effective traffic capacity* of the line in cps $= f_0 = 1/(2T)$; in bps $= 2f_0 = 1/T$.

Where $T = 0.01$ sec, reversals of sending emf can be transmitted up to 100 bits per sec, or 50 cps. The line acts substantially as a band-pass filter. The time required to establish a new carrier amplitude, or a shift in frequency, at the output of such a line or filter is inversely proportional to half the band width[4]—that is, $T = 1/(2f)$.

The arrival curve of a square-top modulated a-c pulse for telegraphy takes twice as long an interval to build up, since in this case $T = 1/f_0$. For equal band widths, d-c telegraphy will theoretically handle twice the information per unit time as double-side-band carrier, and the same amount as SSB transmission.

12. Successions of Pulses on Channels. An understanding of the mechanism of signal transmission over wires is facilitated by considering application at a point A of ungrounded 60-cycle sine-wave a.c. to a metallic pair occupying fixed adjacent pin positions on a pole line joining A with B, 100 miles away. At B, a polar *undulator*

(pen-record galvanometer) traces square-topped alternations produced from the plus-minus contacts of a relay responsive at *B* to *A*'s alternator. The circuit thus demonstrated is capable of being worked at a speed of 60 cps or 120 bits per sec. The bits are the alternations above and below the center line on the undulator tape. They may be given separate identities of mark (M), space (S), to represent the two sine-wave polarities *plus* and *minus* going out from *A*. *B*'s record of the run is therefore . . . MSMSMSMSM . . . .

If *A* were equipped with an electronic *pole changer* that would reverse the alternator polarity every cycle, *B*'s record would read . . . MSSMMSSMMSSMMSSMM . . . . So far as the line and undulator are concerned they would be working momentarily at
FIG. 3. Arrival curves of 22-millisec S-M and M-S reversals. Note: propagation time, per Table 1, column 5, for 150-mile carrier section on aerial pair is 0.8 millisec; load 50% for carrier repeaters; add 1 millisec for vehicle band equipment—total 2.2 millisec. Local equipment response time additional.

30 cps, or half the working frequency. But the number of intelligence bits per second transmitted remains at 120. So far as the capability of the line to handle signals is concerned it is still a 60-cps line because it must be prepared at any time for *A* to switch out his pole changer and revert to the first pattern.

By synchronously "keying the field" of *A*'s alternator, any combination of *M/S* signals could be sent, including the text of telegrams. A different means of modulation is ordinarily used, in accordance with a teleprinter code, but whatever the means, *B*'s record in handling information would consist of seemingly random combinations of single amid multiple pulses . . . SMMSMSSSSSMMMSMMSMSSSSMSS . . . . . The line has no function other than to transmit faithfully on a time scale each and every *transition* S/M and M/S. Between MM or between SS, the line has no function to perform. The fastest sequences, MSM and SMS, are the ones which tax the capacity of the line to perform; hence a.c. in cycles per second at half the bits-per-second rate tests the line for capacity performance.

13. Characteristic Distortion. The behavior of a polar-operated line and its equipment to changes of polarity is such that the poled arrival curves, upward and downward, normally assume the same shape and a symmetrical position about a horizontal mid-axis, as shown in Fig. 3. The receiver, or its line relay, is presumed to overcome the reverse strength of its biasing and close at a point C on the upward curve just above the axis and to submit to the strength of its biasing and open at a point O on the downward curve about an equal distance below the axis. The horizontal distance between C and O measures the length of the marking (M) pulse initiated by upward-arrival curve S/M; the distance from O to C_1, the corresponding point on the successive S/M curve, is the length of the spacing (S) pulse initiated by downward-arrival curve M/S. Under conditions of symmetry, as would obtain if square-topped a.c. were being transmitted, $C - O = O - C_1$.

Operation would become asymmetrical if, in effect, the axis, carrying the receiver operating points, were raised or lowered, causing them to fall asymmetrically on the arrival curves. This would be the case, for example, if an S/M transition should start from the steady-state level and an M/S transition should take effect before the entire upward interval T had elapsed (that is, during a changing-current transition). The axis, in effect, would be raised and $C - O$ would be shortened to the benefit of $O - C_1$, producing *positive characteristic distortion. Negative characteristic distortion* could similarly be created by virtual lowering of the axis by delaying reversal until the overshoot transient point had been reached. Anything which causes the axis to float up and down the arrival curves will cause characteristic distortion, *i.e.*, the type of distortion stemming from line characteristics (see Chap. 24, Sec. 41).

The principal cause is the occurrence of a succession of like-polarity bits, tending to alter the usual points on arrival curves where reversals take effect.

It will be noted from Fig. 3 and the discussion of Sec. 11 that the complete arrival curve includes tailing, or holdover, transients which are ignored when the impulses of opposite polarity are spaced as closely together as the rising portion of the curve permits. In case an S/M transition is followed immediately, not by an M/S reversal but by another M pulse, the holdover transient of the first pulse will assume additive importance, and a succession like MMMM (or SSSS) will compound the effect, "charging" or "blocking" the line to a polarized bias or permitting the establishment of d-c flow. Under ordinary land-line operation this effect does not require mitigation but demands that account be taken of it in measuring components of the distortion characteristic of the response, "memory," and nonlinearity of the line parameters and terminal apparatus. Bramhall[1] calls it "previous-history" distortion, measures its departures from the normal crossovers of Fig. 3, and notes that good engineering practice holds characteristic distortion within ± 1.0 millisec per carrier section of line.

Since the line characteristics produce normally symmetrical polar arrival curves, any characteristic distortion effects will be the same for SS as for MM, for SSS as for MMM, etc. Since the effects are a function of line parameters, they do not tend to vary from day to day except as temperature and moisture change the line parameters.

In submarine-cable practice, holdover transients possess sufficient comparative values to necessitate measures[2] to prevent the frequently occurring SSSSS signals (the *idling* channel condition of a multiplex) or the less frequently occurring MMMMM (*rub-out* signals) from biasing the cable. This is accomplished by making corresponding polarity changes in the transmitters and printers at the circuit ends so that such successions will be split between the second and third pulses and be sent to line in the form $+ + - - -$ or $- - + + +$.

14. Bias Distortion. Referring to Fig. 3, bias distortion, like characteristic distortion, has effects upon the relative lengths of $C - O$ (M) and $O - C_1$ (S) which may be visualized by a raising or lowering of the axis. In the case of bias distortion, however, the causes are due mainly to unequal M and S voltages or line current, ground potentials, or unintentionally biased relays—causes which are watched and corrected by

[1] Bramhall, *op. cit.*
[2] Haglund, H. H., and A. W. Breyfogel, Thyratrons in Loaded Cable Multiplex, *WUTR*, **3**, 34, 1949.

alert maintenance and which tend to vary from hour to hour. Bias distortion lengthens all M bits alike and correspondingly shortens all S bits alike, and vice versa.

In *neutral* operation but not in *polar* operation, the line shunt parameters, especially leakage conductance G but also ground capacitance coupling C, produce differently shaped arrival curves for the S/M transition than for the M/S transition, thus varying the relationship between $C - O$ and $O - C_1$ without altering the axis position. Such changes may be brought about by rain or fog.

In other neutral operations the arrival curves remain of identical shape. Changing the relay biasing current (or retractile spring) in effect raises and lowers the axis with effects on relative length of mark and space already described. Varying line current by raising transmission voltages will raise the height of the figure, T remaining constant, thus virtually lowering the axis and requiring a biasing readjustment.

The arrival curves are of identical shape in all polar operations. If the marking current is weak because of impressed voltage or earth current or ground-potential differences, the axis will be raised with respect to the curves and a bias will result unless the axis is lowered to mid-point. Relay bias will have effects similar to unequal poles of emf. Correction lies in relay bias adjustment or equalization of effective polar battery.

The circumstance that identical arrival curves exist in polar operation accounts for its immunity to trouble while circuit constants vary—especially leakage conductance as affected by wet and dry weather.

Bias and characteristic distortion are cumulative; together they are given the name of *systematic* distortion. A third important element in total distortion, called *fortuitous* (Sec. 18), involves external circuit influences from adjacent communication circuits and neighboring power-supply lines.

15. Ground Function in Transmission. In an ideal situation independent circuits would contain no electrical elements in common, no coupling, perfect symmetry or balance, and hence no spurious influences from outside. The proximity of all circuits to the ground, however, definitely precludes perfect symmetry and hence perfect balance. Examples of unbalance already considered are (1) the aspect of characteristic impedance of a transmission line when one of its two conductors is the ground; (2) the function of the ground in producing unequal shapes of arrival curves for the make-and-break of neutral operation; (3) the *proximity effect* of many wires on a pole line in altering the capacitance parameter of grounded circuits. In addition the earth disturbs circuit symmetry by entering into the formation of inductive loops containing the wires, and also by the role of subsoil conductivity in introducing spurious currents from one circuit into the other.

Because some of these aspects of circuit proximities and unbalances are geophysical, the properties and functions of grounds in transmission assume great significance.

The resistance of the path in the earth of a d-c circuit of which the earth constitutes one of the two conductors is zero ohms because the specific resistance of the earth's material,[1] whatever it may be, is made negligible by the earth's size. Thus, if a loop consisting of a transatlantic cable and the earth is measured, all the d-c resistance is accounted for in the copper cable conductor, and zero ohms in the earth as a conductor. The earth in fact even constitutes a d-c shunt of the large steel armor wires in contact with the sea.

Since earth's $R = 0$ the potential drop $IR = 0$. It follows that all perfect grounds are at zero potential. The d-c power loss in the ground $I^2R = 0$.

While good connections to ground[2] are obtainable in water, a perfect ground connection is usually to be secured only with difficulty in soil[3] (*cf.* radio ground systems). To minimize ground resistance, resort is often taken to laying multiple grounds in

[1] Card, R. H., Earth Resistivity and Geological Structure, *Trans. AIEE*, **54**, 1153, 1935.

[2] "Grounds," Bureau of Standards Technical Paper 108. J. G. Biddle Co., "Manual for Ground Resistance Testing," 25-J, 1952. Knowlton, A. E., "Standard Handbook for Electrical Engineers," Sec. 14, pars. 70–73, McGraw-Hill, 1941.

[3] Hausmann, E., "Telegraph Engineering," Van Nostrand, 1922.

parallel. From each ground or each set of grounds, *multiple paths* for current through the subsurface may be postulated, flowing from the ground rods or plates into the zero-resistance earth itself. Potential gradients exist, of course, to support the flow of current along these paths, and may become involved with the potential gradients in the grounds of "foreign" systems (Secs. 17, 18).

Because of the relative magnitude of its reactive component compared with its resistance, the earth as a conductor presents a definite impedance to a.c., of practical importance[1] even at 50 cps; and there will be a corresponding power loss in the ground. The fact that a-c potential gradients can be maintained even in sea water is demonstrable by the use of amplified currents from the electrodes of leader gear, used as probes, to locate submarine cables through their external fields.[2] With increases of frequency, cable-armor wires at the sending end carry an increased proportion of the a.c. (regardless of direction), and the sea water in parallel with them less, causing an increase of resistance (steel having replaced the earth) and a decrease of circuit inductance[3] in the system's second conductor (not too accurately referred to as sea "return").

Protector grounds for communication circuits[4] need be no more elaborate than the familiar water-pipe ground. In a different class are those used where current must be dissipated, such as for central telegraph office grounds for circuits, and grounds for cathodic protection of cables against electrolysis.[5] In the latter type the current must flow in the earth without corroding or polarizing the grounds, over long periods of time and without increasing R. Ground resistance decreases with number of electrodes and their diameter and with the depth of driven ground, and it varies with soil conductivity, which may show seasonal variation. A typical office ground measures 0.1 ohm, of which 90 per cent is concentrated in a radius of 20 ft.[6]

Formerly used methods of measurement of grounds by d-c Wheatstone bridge, involving three grounds taken in series pairs, were open to difficulties due to polarization and foreign currents encountered and have been superseded by use of a-c meggers.[7] In wire telegraphy, measured ground impedance is conveniently to be integrated with that of the ground lead or bus.

Although perfect grounds are not always obtainable, they may be assumed in certain situations. Thus a perfectly grounded rod or plate, from an engineering viewpoint, may be assumed to be at ground, or zero, potential relative to all electrically charged bodies, no matter where located on the surface of the earth. Apart from other influences, a wire connecting two such grounds will be "dead" because of the zero potentials existing at its ends.

Ground Currents. Assuming two faultless grounds at points remotely situated, a measurable current, nevertheless, will often flow in a wire grounded at both points. Such currents may flow from three influences:

1. A more or less steady potential difference[8] which exists day after day and which is best taken care of either (*a*) by a ground corrector that applies a counter emf to circuits containing an abnormal ground potential, capable of following and offsetting it, or (*b*) by running a ground wire to a point free of the abnormality, as a cable sea-earth is sometimes reached 100 miles seaward through bicore cable. This condition is usually associated only with man-made electrical effects like those produced by use of the ground as one conductor of electric-railway power. Here, through peculiarities of the subsoil, electrical-potential strata are set up partially insulated from the bulk of the earth's structure.

2. A fluctuating-polarity emf generated dynamo-fashion in the line by moving terrestrial electromagnetic fields—in extreme cases definitely associated with *magnetic storms* and their manifestations of aurora. These are often called *earth currents* or "ECs" but it is not necessary for engineers to assume that their manifestation is due to an actual upsetting of the earth's normal equipotential surface. Mitigation consists in replacing the earth with a parallel wire as the mate to the other conductor; the induced emfs will then be the same and in phase in the two conductors and will cancel. Because of their slow roll (say, 10 to 20 cycles per hr) even a grounded circuit like a submarine cable will work through the disturbance if its (practically d-c) characteristics are separated from the signal currents by employing transformer coupling between cable and amplifier.[1]

3. *Static*, of consequence to wire operations whenever its frequency components reach down into the telegraph signaling spectrum, and whenever its cumulative power at a communication terminal is high enough to break across the tolerable noise-signal ratio. The earth's function in such a power transfer is the same as in radio, the wire (more often submarine cable) line acting as a receiving wave antenna.[2] Lightning has effects on transmission of a higher order of magnitude than static.

Cross Talk Caused by Ground. One way in which the earth disturbs symmetry between communication circuits is as follows: If wires *ab* comprise working circuit 1, and common conductor *a* is used to make up *ac*, *ad*, *ae*, and working circuits 2, 3, 4, the inductive coupling will be closer, and consequent interference between the several circuits greater, than between, say, *ab*, *cd*, *ef*, *gh*, in separate pairs. The close inductive coupling of any two circuits may be looked upon as though one loop were a continuation of the other in the manner of the primary and secondary of an autotransformer. The use of a common conductor *a* for several circuits describes, of course, a pole line loaded with neutrally operated earthed circuits using a common battery. Such systems were once in universal use in telegraphy, but because coefficients of circuit coupling go up with frequency, intercircuit cross talk became intolerable for telephone[3] use wherever parallelisms existed for appreciable distances, and the use of metallic loops and pairs was employed to remove the inductive-coupling influence of the ground. Modern telegraph circuits, operating in the v-f range, likewise universally use metallic pairs.

Another way the earth enters into the creation of a cross influence of circuits due to their proximities or parallelisms is linked with the fact that multiple current paths exist in the subsoil along which circuit energy reaches the earth as a conductor. It follows that potential gradients exist in the subsoil to support the flow of current along these paths, and that they may become involved with the potential gradients set up by virtue of the presence, in the same body of subsoil, of the ground systems of neighboring communication or power-supply circuits.[4] Coupling currents will be set up in conductive soil between all points of unequal potential, resulting in the introduction of spurious energy into each circuit by the other. This type of ground coupling is the most serious cause of power induction into communication circuits.

16. Power Induction. Extensive parallelisms between power-supply lines and wire-communication circuits are avoided wherever possible to reduce power interference in the communication lines.[5] Cooperative measures by the industries involved to avoid interference has become known as *inductive coordination*,[6] in the pursuit of which the engineers recognize the public's right to both services at minimum over-all cost.

For convenience, inquiries are directed between (1) the lower-frequency effects[7] of

60 or 25 cps and their harmonics and (2) the effects of power-line abnormalities of higher frequency[1] due to switching, insulation breakdown, and lightning transients.

As noted in Sec. 15 the effects of all influences are multiplied whenever they involve common ground coupling or potential gradients in the earth.

If a three-phase power circuit is balanced as to its parameters and its loads, the vector sums of the phase voltages and currents to ground are zero. A fault to ground on one phase[2] will produce vectors representing residual voltage and current, no longer zero. Residual currents are equivalent to single-phase currents applied to a circuit composed of the ground and all three power conductors in parallel. The effects on communication lines are due to the physical size and electrical values of the coupled loop, and the magnitude of the currents and potentials in the subsoil. The extraneous voltages which appear are a function of the exposure conditions of the current and voltage of the power line, the fundamental and harmonic frequencies, and the degree of balance in power and communication lines.

During normal power-system operation, telegraph carrier circuits are most affected by harmonics of the power-line fundamental frequency, while d-c telegraph is more susceptible to the fundamental and third harmonic.

Transient voltages at their highest are induced into communication circuits when faults or abnormalities occur on paralleling power lines, frequently because of lightning. Such transients may be sufficient to operate protective equipment on the communication circuits.

Specific remedial measures include reduction of coupling by providing greater separation, improved balance of power-line voltages and current or of metallic communications pairs, transpositions, shield wires, use of cable, resonant shunts, limitation of fault currents, self-restoring arresters on communication circuits, and *neutralizing transformers*.[3] The latter have one primary winding and from 2 to 100 pairs of secondary windings to accommodate the communication circuits.[4] The primary winding is energized by a voltage of such phase and magnitude as to neutralize the voltage induced in the telegraph wires connected to the secondaries, and this may be acquired by direct connection to a low-impedance pilot wire subjected to the same exposure or by indirect connection through tube amplifiers.[5] The primary winding may be tuned to the interfering frequencies to increase its effectiveness and to reduce the cross talk between the communication circuits.

For the treatment of lesser cases such as individual instruments and short patron's loops, tuned resonant shunts are helpful where signaling speeds are 30 cps or less and the interfering frequency is 60 cps or a harmonic thereof.

General measures of control are directed toward minimizing the influence of the power circuits, decreasing the susceptibility of the communication circuits, reducing the coupling between the circuits, and various combinations of these factors.

Economics, reflecting high costs of modern power and communication lines, often dictates acquisition of private rights of way for them, thus reducing parallelisms by the avoidance of highways. Some railroads provide common rights of way, creating long exposures of power and communication lines.[6]

17. Telegraph Cross Talk. The coupled interference of energy carried by one communication wire or circuit with that in a parallel communication wire or circuit is descriptively similar to the power-interference problems discussed in Sec. 16 except that parallelisms and proximities cannot be avoided. In telephony and carrier teleg-

[6] A thorough technical treatment of inductive coordination is to be found in Recommendations 7-7 of the Association of American Railroads, "Discussion of Fundamental Factors Involved in Inductive Coordination and of Remedial Measures Applicable under Various Conditions," and in Recommendations 7-8, "Practical Procedures for Investigating Inductive Effects on Communication Facilities."

raphy such interference is known as cross talk; in d-c telegraphy it is known as cross fire.[1] It is customary to think of both as inclusive of both power and communication interference components. Cross fire, as a separate subject, has gone out with the day of heavy leads of grounded time-division-multiplex circuits.

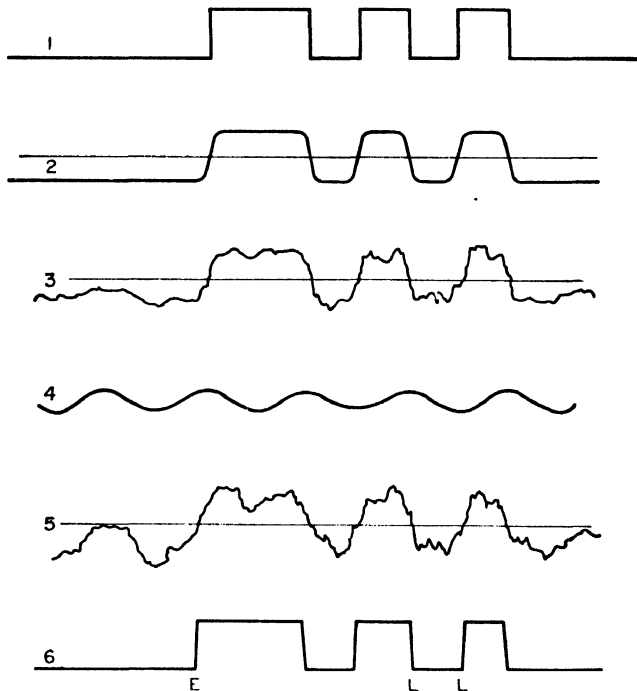
The functions of unavoidable subsoil current interactions in increasing interference have been sufficiently emphasized; the observations apply equally well to cross talk. In communication parallelisms, partial grounds occur wherever shunt conductance is affected by partial failure of line insulation, inducing cross talk.


Fig. 4. Effects of interference on transmission. (1) Signal as transmitted. (2) Rounded-off received signals without disturbance, (3) with telegraph cross fire. (4) 60-cycle a-c power interference, superposed (5) on signals and cross-fire (3). (6) Early (E) and late (L) relay displacements due to interference.

Apart from leakage, any two conductors, one of which carries signals, are coupled electrostatically by shunt capacitance directly between them and by series capacitance between each and ground; at the same time they are coupled electromagnetically by the moving field associated with the wave fronts in one conductor inducing an emf in the other. Induction results from both types of coupling. Ordinarily the two effects are measured as a whole and included in cross talk. Figures 4 and 10 show how telegraph signals are distorted by power-supply and telegraphic cross talk.

With spread of the use of carrier frequencies for intercity telegraphy, the telegraph system now operates, as does the telephone system, relatively free of grounded circuits. Aerial and multipair cables and open-wire lines constitute aggregations of metallic loops.

Telegraphic cross talk into telephone circuits is aggravated by any great disparity

[1] Shanck, R. B., Neutralization of Telegraph Crossfire, *Bell System Tech. J.*, **5**, 418, 1926. Gould, K. E., Coupling between Parallel Earth-return Circuits under D-c Transient Conditions, *Trans. AIEE*, **56**, 1159, 1937.

between signaling voltages used on the two systems, so that practice is to limit telegraph signaling current in the telephone plant.

In aerial and underground cable, the pairs are laid throughout each unit length in layers or in bunches, adjacent pairs having different lengths of twist to prevent cross talk. Pairs in the cable center are frequently twisted together to form *quads.* An effort is made in splicing cables to have each pair occupy an approximately average position with relation to the grounded sheath that every other pair occupies. Equality of external induction experienced by each of the wires in a cable pair is enhanced by close spacing; hence pairs in cables are less affected by induction from nearby pairs than are those on pole lines.[1] A lead cable sheath also acts as a substantial (50 to 100 per cent) *electrostatic shield* against the minor electric-field component of power-line interference.[2] The outer conductors themselves also act as a collective shield for the inner wires. Similar external mutual shielding effect may be observed in a pole line as a whole in relation to any pair included.

In open-wire line construction the tendency is away from uniform 12-in. spacing of the 10 pin positions on each crossarm toward 8-, 6-, and even 4-in. separations within each pair and correspondingly increased separations between pairs. Closer spacing is dictated by inductive considerations as carrier frequencies increase; collateral benefit is secured by a decrease in L, which (*cf.* Table 2), although increasing the attenuation constant A (which can be retrieved by terminal or repeater amplifier gain), desirably increases wave-front velocity and decreases the phase shift B.

Equalizing and stabilizing of the two series parameters R and L of the two conductors constituting each pair, and balancing the shunt parameters C and G of all pairs in relation to each other are the desiderata in reducing mutual interference between pairs. It is essential that the two conductors of a pair be of the same material and gage at all points on the line. In stabilizing R, the rule is to solder all terminal joints in the circuit, to make joints in cable by twisting, and in aerial wires to use cold-flow compression-sleeve joints. Jack-terminal machine wrapping techniques are replacing soldering in some applications. Equalizing L involves the equispacing of any loading, continuous or lumped, applied to the line.

Transposition. Shunt-parameter balancing is accomplished through transposing conductors, in the relative pin positions they occupy on the crossarms, as their course continues from pole to pole. For many years such pin-position permutations have been widely used in telephony. With adoption of metallic carriers, *transposition patterns* have assumed equal importance in telegraphy.

A former method of securing approximately equal inductive exposure, used on open-wire grounded telegraph lines, was to route single conductors throughout all pin positions on the line in an attempt to equalize its linkages with all other conductors. Present-day transposition patterns do not follow that principle. With the exception of the two side circuits and phantom of a four-wire phantom group, which follows such an equal-exposure pattern but the use of which for telegraphy has nearly ceased, transpositions are confined to the two conductors of each pair; the pair continues to occupy the same two pin positions throughout the length of line.

Two guiding principles may be recognized,[3] working concurrently: First, it is sought to prevent loss of energy by induction from the pair to all the rest of the wires on the line considered as a group and having a general relationship with the ground. This is accomplished by frequent, more or less constant, interchange, using extra types to be described; the extra pattern for one pair will not be unlike those for all others. Second, it is sought to use a wide selection of different *fundamental types* so that each pair will appear distinctive in relationship to most others, and so that, especially respecting its near neighbors on the line, it will present true relative inductive cancellations or offsets.

The first principle enunciated has direct bearing upon attenuation and noise-power ratios in a pair. If energy can be held within a pair rather than lost to the line as a

[3] Courtesy of T. F. Cofer, Western Union Telegraph Company.

whole it not only will increase received power on the pair but will decrease the totality of noise on that pair received from all pairs on the line as a group.

The second principle focuses attention on linkages between one pair and the others individually, especially neighbors. It works hand in hand with physical layout of crossarms and pin separations and goes even to decisions as to which side of each insulator shall bear each conductor. As frequencies have gone up for carrier operation, the tendency has been to increase crossarm vertical separation from 20 to 24 and 30 in. Conductor separations in a pair have come down from 12 to 6 in., and spacing between adjacent conductors of contiguous pairs on the same crossarm has increased from 12 to 30 in.

Extremes of inductive coupling take place: (1) between pairs mounted adjacently on the same crossarm, for despite the fact that their loops lie in the same horizontal plane, one of the conductors of a pair lies nearer than the other to an interfering pair, producing an unbalanced configuration; (2) between any pair and the one just above or below it on the next crossarm, for coupling occurs by transformer action between the loops, regardless of their balanced configuration. The transposition designer must pay particular attention to such exposures.[1]

Consideration also has to be given to the interference introduced in proximate pairs by waves traveling in opposite directions, leading to a sharp difference between the interference levels of strong near-end (or sending-end) cross talk (where an attenuated received wave is being mixed with strong induction from outgoing signals) and weaker far-end (or receiving-end) cross talk (where both the wanted signals and unwanted noise are traveling and are being attenuated in the same, incoming direction). Near-end cross talk at carrier frequencies is so difficult to cope with in cable that separate directional cables are often employed in four-wire connections to avoid it,[2] while on open wire-line sections, though two-wire carrier is used, a strict frequency-cleavage pattern is employed to separate east and west transmissions. Transpositions may then be designed to conform to frequency separation, and near-end cross talk will be minimized.

FIG. 5. Paired pin positions, "40-wire" line, facing direction of ascending pole numbers. 5-6, 15-16, etc., are pole pairs; others are side pairs. Wire tie positions on insulators indicated. Figures below crossarms denote spacing in inches. Letters with subscript figures above lower crossarms illustrate fundamental and extra transposition patterns employed. (*From Monograph* 2520, *Courtesy Bell System*.)

To illustrate only a few of the expedients employed in transposition engineering, a design specialty, attention will be confined to a single example. In a typical 8-span transposition pattern of 40 wires borne on the 4 crossarms (Fig. 5) of a pole-line trans-

Fig. 6. Fundamental transposition patterns, typical of 8-pole (8-span) units between transposition poles; 32 transposition poles per 256-span section (6.4 miles). (*Courtesy Bell System.*)

position section 6.4 miles in length (257 poles, 256 spans, span length 130 ft, 40 poles per mile), all 20 pairs on the line are subject to possible fundamental transposition of pin positions at least every eighth pole (every 8 spans, or 32 possible transpositions throughout the section length), following one of the 32 types, *a* to *p* and *A* to *P*, of Fig. 6. Thus, pair 13-14, transposed as type *a*, would be transposed at every eighth span, while 27-28, following type *A*, would be transposed at every sixteenth span.

It should be noted that a pair of type *b* would have no relative transposition to a pair conforming to type *a* until the 128th pole (at mid-section) was skipped by the type *b* pair, after which the pairs would be in opposition. This relative opposition itself can be diagramed, as type *O* of Fig. 6. Each combination of any two transposition patterns will be found to have one relative in Fig. 6. The object of *relative transposition* with other pairs is to subject each pair, farther along the line, to counteracting influences in the right proportions after each exposure to induction by parallelism with nearby pairs.
FIG. 7. Extra transposition patterns. Widely used extra transpositions occur within 8-span fundamental transposition intervals. (*Courtesy Bell System.*)

The frequently transposed patterns, like *a* to *f* of Fig. 6, also serve the other purpose of transpositions—to prevent loss of energy from the pair to the line as a whole. As frequencies go up and the point is approached where there is a tendency to radiate energy, transpositions based on the fundamental eight-span pattern prove inadequate. Further refinement takes the form of the extra types of Fig. 7. The *septuple extra* would involve transpositions on every pole or in every span; in practice, the employment of extras rarely needs to go beyond the *quintuple extra* type.

The transposition configuration of one section of a line is not necessarily that of adjacent or successive sections. *Transitional patterns* are employed, and separate consideration has to be given every portion of open-wire line marked off by discontinuities such as points of juncture with branch circuits, impedance mismatches, pole-line configuration changes, points of power-induction exposure, and circuit terminations.

The function of transpositions is to prevent energy losses and to equalize exposures; exposures are functions of moving electromagnetic fields and therefore of applied emfs, attenuation *A*, and phase shift *B*, in the interfering and interfered-with conductors, bringing with them a varying rather than a constant influence as a wave proceeds along a line. These variables must be taken into account.[1]

The idealized illustration chosen makes no allowance for difficulties encountered in actual lines,[2] where unequal pole spacing, variable sag in line wires, and nonuniform spacing of crossarms, pins, and wire ties require attention of the transposition designer. Many older transposition schemes were worked out on 8-mile instead of 6.4-mile sections, and on 10-span instead of 8-span fundamental patterns, calling for compromises in the extra types of transpositions. The cumulative effect of these variables does not present insuperable transposition difficulties for lines and pairs carrying 30-kc signals but is important enough, with 150-kc carriers, to dictate resetting of poles, resort to the use of accurately placed span-transposition brackets, or rebuilding of lines.

To complete consideration of interference, note should be taken of measures adopted to eliminate the interference of wire-communication circuits and apparatus with radio receivers,[3] especially in a-m broadcasting. Telegraph wires and telegraph power-

supply conductors act as antennas for sporadic r-f emissions from sparking-relay contacts, teleprinters, and other apparatus in telegraph and customers' offices. Of 25 types of corrective networks employed, three representative types are shown in Fig. 8. The spark killer A is most widely used and is placed as close to the contacts as possible with short leads; a contact-protecting filter B is used to eliminate interference in teleprinter applications; a filter C eliminates interference of generators via power-supply lines.
FIG. 8. Measures for prevention of interference to radio: (A) contact-shunting spark killers; (B) contact-protecting telegraph interference filter; (C) power-line interference filter.

18. Fortuitous Distortion. The accumulated effect of all the elements which have been described as contributing to induced interference, or noise, in communication circuits is called fortuitous distortion. By interaction of noise power N with the arrival curves of residual signal power P, the curves become distorted in shape; the points where they cross the horizontal line which defines the operating level on the arrival curves are displaced an amount measurable in milliseconds or microseconds (or expressed as a percentage of the signal length) from datum points established by the receiver's *sampling* or gating circuit. A representatively safe signal displacement in the first carrier section of a line, due to fortuitous distortion,[1] is 5 per cent of 22 millisec, or 1.1 millisec.

The ratio N/P is called the noise ratio; P/N is the signal-to-noise ratio; the percentage of noise is $100N/(P+N)$. Noise in telegraph circuits, and its influence upon fortuitous distortion, is characterized by long intervals during which its background effects remain within a constant range, punctuated by erratic jumps to higher values. The peaks determine the circuit *margin*.

FIG. 9. Differential duplex, one-wire and ground, polar. If Z of the artificial line AL is made equal to Z of the main line beyond P, each station's relay will be unresponsive to its own key but will remain responsive to the distant station's key.

A source of interference appearing as a physical-circuit noise component but not falling into any of the classifications enumerated so far is that introduced into the receiving end of a duplexed circuit by the transmitting going on at the same end (see Fig. 9). This effect results from inexact impedance matching (called *balancing*) of the artificial line AL, with the main line ML at all fundamental and harmonic frequencies included in the transmitted wave form (usually square-topped d.c.). The

[1] Bramhall, F. B., Transmission of Business Machine Data over Standard Telegraph Channels, *WUTR*, **10**, 89, 1956.

mismatch causes points P and Q to be at different potentials instead of at the same potential when the battery of either pole is applied to the apex X; the receiving relay R_a, in consequence, senses spurious locally generated interference with the wanted received signal coming in over the line conductor at point P and taking a double path to the second conductor through X and Q.

Because of the similarity of its effects and difficulty of separating them from inductive disturbances in measurement, duplex unbalance is usually included within the category of fortuitous interference.

Trends in the communication industry are away from duplexed and other electrically balanced telegraph circuits of all kinds, partly because of the expense and lost time associated with keeping them sufficiently in balance to prevent self-induced circuit noise. Among such balanced circuits are derived *composite* grounded d-c telegraph circuits on each of the two conductors constituting a metallic pair in telephone use; *phantom* pairs for telegraph carriers derived by mid-tapping the line-coupling coils of two ungrounded *side pairs;* and *simplex* one-way telegraph circuits one of whose conductors is the ground and the other a metallic telephone pair the line-coupling coils of which are mid-tapped. Four-wire connections for two-way carrier are preferred to frequency-divided two-way circuits in multipair cable. The availability of undersea amplifiers has accelerated the abandonment of duplexed submarine cables except on single-cable routes. Radiotelegraph employs one-way circuits.

Hence there has been a growing avoidance of electrically balanced circuits. Even when full two-way teleprinter duplexes are set up, resort is often had to "half duplexing," or back-and-forth operation alternately. In the balanced configuration of Fig. 9 this is accomplished by introducing a differential control relay[1] at the apex in series with the relay shown, the function of which, in connection with a neutral relay and a differential break relay, is to deny simultaneous two-way use of the line to the operators at the two ends without denying to either of them, by manipulation of his sending keyboard, the ability to break up and hence to stop the other's transmission. Such an arrangement is less critical as to maintenance of duplex balance than one designed to afford continuous two-way use.

19. Measurement of Distortion. Several distortion-measuring instruments and methods have found acceptance. The device most widely and pragmatically used is the teleprinter itself with its incorporated ranging scale.[2] More accurate findings may be made with electronic testing equipment.

In Fig. 10, S-M and M-S transitions are represented by arrival curves which show the effects of distortion. The output of the main line relay is seen to be broken up at O and C. Such a signal, though it has indefinite boundaries, is useful, in the middle portion MN, to determine definitely the polarity of the signal. Multiplex receiving brushes (or, in the case of start-stop teleprinters, the receiving cams) are arranged to sense the polarity of the signal only in the middle of the useful portion PQ. That much (one-half) of the pulse length is adequate for the local operation of relays and printers, but for onward transmission into another line or into a carrier section the full-length pulse PR is *regenerated* by locking up, in or after the interval QR, an extension of the signal sampled during the interval PQ.

Start-stop teleprinters are equipped with a *ranging arm* and associated scale, attached to the starting mechanism of the receiving system, to refine the orientation of the receiving cams to the middle portions of signals.[3] With this arm the starting latch may be rotated with respect to the position of the No. 1 receiving cam, by this means determining whether the mechanism will be actuated by the leading edge, center, or trailing edge of the signal. The total travel of the range arm is made 1.2 times the length of one signal pulse; so the scale is graduated into 120 points, 100 points range being ideal for perfect signal and perfect mechanism. Wear of parts and

instabilities will bring the range down to 80 before the line is connected to the teleprinter, not necessarily centered at 60, mid-point on the scale.

The *ranging test* is regularly performed before the circuit is opened for traffic, and at other times as errors in received copy reveal loss of range. By rotation of the range arm to its two extreme positions, the points on the leading and trailing edge of the signal are determined where false signals appear, and the scale is read in each case. The range arm is then moved to and locked at the point on the scale which is the arithmetical
FIG. 10. Arrival curve, with induction, showing response of relay contacts and sampling and regenerative action of receiving brushes and faceplate. The break-over current I_b is that required in the relay windings to prevent contact tongue from breaking contact (chatter) due to inductive disturbances. The faceplate segments can be oriented as desired to the middle of incoming signals.

average of the upper and lower limit readings. The *range* is stated as the difference between those readings. It will remain valid until some change in transmission occurs to narrow it or to shift it off center, in which event a new range must be taken and its center determined.

More accurate measuring methods[1] are concerned with the correction of distortion due to *envelope delay*, the first derivative of the phase constant B with respect to $2\pi f$, over the significant range of frequencies encountered in facsimile or v-f transmission. A number of representative papers have been published on the measurement of distortion.[2]

Because of many differences in their causes, characteristics, and simultaneity of occurrence, the contributions of characteristic, bias, and fortuitous distortion are not directly additive as to sign, with respect to either a single line section or a succession of them. Within a single section, generally speaking, bias which is constant is additive to the rms of characteristic and fortuitous components, which are erratic. From section to section, characteristic distortion tends to be cumulative, since unfavorable signal combinations will adversely influence every section alike, while bias and fortuitous elements will assume rms relationships. For 100-wpm teleprinters working over a single carrier section, good engineering practice will specify limits of 1 millisec signal variation (7 per cent of the 13.3-millisec signal length) for characteristic distortion, and 5 per cent each for bias and noise; the total is not 17 per cent but less than 13 per cent because of rms relationships.[1]

Rms distortion losses up to 13 per cent of the length of a signal, disclosed by a teleprinter on its range scale or otherwise measured, are well within the limits of safety from errors. Variations exceeding 35 per cent will cause errors. It is the practice to regenerate signals completely whenever, after three or four tandem carrier interconnections, the variations exceed 30 per cent of full-length signal.

20. Accuracy of Transmission. Perfect transmission requires that all the type bars of all the receiving teleprinters of all the channels on a circuit shall at all times, without error, reproduce the continuing functions of the sending keyboards. While this ideal is never long sustained in practice, it is possible to assign and sustain any required standards of lines up to but not including the teleprinters, provided that no limit is set by economics, that the physical integrity of the circuit constants is preserved, and that the plant is protected from acts of God.

The Bell System employs telegraph *transmission coefficients*[2] to epitomize distortion conditions affecting transmission accuracy in each component of its end-to-end interconnections. Such components comprise sections of line, by types; loops, switchboards, and repeaters. The coefficients run from 0.0 to 10.0; like decibel attenuation figures, they are additive, component by component, so that a circuit total coefficient may be directly ascertained as the sum of the coefficients of its parts. The highest-quality lines,[3] such as a v-f carrier teletypewriter section, will therefore have a low coefficient, like 1.5, while an inferior grounded half-duplex line to an outlying point will be weighted 4.0 or 5.0. An entire circuit is considered satisfactory for commercial service if the coefficient $\leqq 10.0$. *Regenerators* are inserted to divide circuits with a coefficient > 10.0; working limit between regenerators is 7.0.

Line coefficients reflect all causes of distortion and degrading, but not failures, disconnects, accidents, and interruptions. They are numerically the product of the rms values of the several distortion influences multiplied by a conversion factor determined by normal-law distribution of the probability that a limit of 35 per cent signal distortion (which produces errors) will be exceeded in one case out of an arbitrary number of signal transitions.

Practically, coefficients are related both (1) to a maximum checkable distortion under normal operating conditions, expressed as a percentage of signal length (*cf.* Sec. 19) and determined over a representative 5-min run, and (2) to the number of characters which may be presumed to be handled with complete accuracy per single errored letter. These relationships are shown in Table 3, adapted from published graphs.[4] The most significant point is the coefficient of 10.0, beyond which a circuit requires attention to render it generally acceptable. Here the average transmission develops only one wrong character in 44,000—equivalent to one error in 12 pages of single-spaced typing, letterhead size, or one error in 2 hr at 60 wpm. All lower coeffi-

cients represent better accuracy; the median is 6.5.[1] The standard mean coefficient for private-line telegraph service is 6.5, with an accuracy performance of one error in 8,000,000 characters; the mean for TWX (teletypewriter exchange interconnections, subscriber to subscriber) is 3.5, because of the prevalence of short hauls and simpler circuitry than in private wire networks; 35 per cent of TWX connections have coefficients of less than 2.0, pointing to line accuracy far beyond 100 billion characters per error due to line transmission (see Chap. 24, Sec. 56).

Table 3. Design Correlation between Telegraph Transmission Coefficients, Distortion, and Circuit Accuracy—Intercity Lines

Transmission coefficient	Private-line services, % of circuits having coefficients exceeding those tabulated	No. characters per error due to circuit	Design max, short-run distortion, %

PLANT RELIABILITY

21. Circuit Discontinuities. A practical consideration in the operation of lines is the occasional occurrence of conductor discontinuity or high resistance, radically affecting R, and of short-circuiting of line conductors, affecting G in some section of a circuit. These are known as interruptions or faults, and they take many forms. Discontinuities due to wire breaks are comparatively easy to locate and remedy by wire or pair substitution in the affected section. High-resistance faults due to poor or corroded joints in conductors or joining of wires to equipment, giving rise to intermittent faults, are avoided by use of proper construction and maintenance techniques[2] and tools, producing soldered joints, cold-flow "welds," and other measures[3] to prevent joint oxidation. The improper use of soldering flux can itself contribute to line faults.[4]

A modern 12-channel 24-repeater carrier, any one of whose v-f channels may be modulated by telegraph signals, contains approximately 6,000 soldered connections

and as many pressure contacts, all of which must function perfectly over long periods of time if trouble-free operation is to be achieved. Defective soldering is a conspicuous offender, particularly evident in new work before the "dry joints" have been discovered by inspection, probing, and shaking. A European method[1] puts suspected joints into tuned mechanical vibration while an amplifying a-f circuit picks up detected side bands denoting variable joint resistance while the equipment is under electrical test.

Other continuity defects arise from defective spot welding in tubes and components; "dry" or "unwetted" rivets; dry contacts; loose or oxidized screw-pressure connections; oxidation or poor contact of tube pins and sockets, plugs and jack sleeves, plugs and springs, mountings and fuses or heat coils, crystal holders, rectifier elements; slide and wire contacts; and broken wire or strands inside insulation. Low-voltage a-c measurement of a good soldered connection is of the order of 0.001 ohm; a "dry" connection may measure 0.10 ohm and up.

FIG. 11. Protector for typical telegraph carrier pair.

22. Crosses and Grounds. Shunting of aerial conductors occurs as the result of improper mechanical tension or sag and consequent contacts, or of introduction of conducting material into the lines. When a third, or "foreign," conductor is in contact, it introduces extraneous emf or drains off current, in either case setting up unwanted wave fronts and current flows. Maintenance gangs working on line repairs employ methods to minimize such *swings*, *hits*,[2] *scrapes*, and *crosses*, as they are called—all sources of fortuitous distortion if they are momentary, of low level, and of so infrequent occurrence as not to put a stop to use of the circuit.

Even on insulated pairs, grounding, either direct by wire contact or through lowered resistance introduced by broken insulators, may seriously disturb the coupling of such pairs to others; on grounded circuits it bypasses transmitted energy normally flowing beyond the point of fault.

Akin to a line fault but perhaps more accurately classed as fortuitous distortion are two recognized effects of vibrating line wires: magnetostriction[3] and varying reactance due to changes[4] in L and C between wires.

23. Lightning Interference. Circuit outages due to open and grounded lines, though actually fortuitous, are not usefully classed as examples of fortuitous distortion because of their masking effect. They do affect measurement of reliability of service if not its essential accuracy. In the same class are lightning, aurora, and foreign

voltages, against which the telegraph plant is partially protected at office distributing frames, at junctions of open wire and cable, and, in aggravated cases, at intermediate cable points.[1]

Figure 11 illustrates the *protector*[2] provided at the office distributing frame for a typical carrier-telegraph-line pair. The instrument fuses are normally of 0.8-amp capacity and are designed to protect the office equipment. In the event of contact with a high-voltage power line[3] which would send a large current through a fused arrester to ground, the line fuses are designed to rupture upon passage of a current of 15 amp for 5 min. At open wire-cable junctions, only high-voltage arresters, 750 to 1,200 volts, are used.

Carrier telegraph systems, operating on balanced metallic pairs, are subject to lightning interference[4] because of the low level of the line currents. Much of this interference is caused by the nonsimultaneous operation of the two line arresters because of minor dissimilarities of the arresters or by imperfect balance of the line pair.[5] By including in series with the pair of arresters of Fig. 11 a coil having two closely coupled and carefully matched windings to form an autotransformer with a grounded center tap, it is possible to enforce simultaneous operation of the two arresters. At the same time the presence of the coil in the lightning-discharge path impairs to some degree the protection afforded by the arresters, so that it is desirable to add a second pair of arresters of higher breakdown known as *guard arresters*. Typical breakdown value for the coil arresters is 350 volts and for the guard arresters 750 to 1,200 volts. The combination is effective in the reduction of lightning hits having a peak value sufficient to operate the coil arresters but insufficient to operate the guard arresters.

Where the physical line wires carry no d-c telegraph services, the coil arresters may be omitted so that the coil affords a permanent drainage path for accumulated static voltages as well as lightning hits. In this case,[6] a reduction up to 80 or 90 per cent of the potential atmospheric disturbance can be achieved.

24. Power Interruptions. As serious as an interruption of a telegraph line is a temporary (even momentary) loss of power supply.[7] Wherever possible two sources of d-c supply are tapped. There is an emergency power plant whose prime mover automatically starts and gets under load when the usual d-c voltage drops below a predetermined amount.[8] A storage battery, normally floating, takes the load over during the 0.05-sec switching interval. In the case of radiotelegraph-beam operation[9] where emergency a-c supply is required, plate-supply capacitors hold the voltage during the 0.1 sec required for emergency a-c vibrator units to take up the load. They hold it for ½ min, by the end of which time the emergency alternator is up to speed and automatically takes over.

25. Pole Lines and Aerial Cable.[10] The integrity of open-wire lines begins with the poles,[11] crossarms,[12] and insulators,[13] which support them. Poles are chiefly of yellow

pine or western cedar. Seven classes have been nationally standardized[1] with dimensions adjusted to give equal strengths regardless of kind of timber. The size and spacing of poles depend upon the expectancy and amount of ice that may form on the wires, the severity of the climate, and the number of wires carried. Based on tests and experience, standard ice and wind loadings for various sections of the United States have been adopted.[2] It is customary in designing lines to provide strengths for the supporting structures that are 2.75 to 3.5 times the theoretical computed values to compensate for the variability and deterioration of poles and to take care of unusually severe storms.

Pine poles are pressure-treated their full length with creosote or pentachlorophenol.[3] Other timbers may have only the lower portion, which rests in the ground, treated.[4] Properly treated poles have a normal life expectancy of 30 to 40 years. At corners, terminals, crossings over railroad tracks, and at the ends of long spans, it is necessary to reinforce the poles by means of guys.[5]

Open-line wires are normally copper, of diameter from 102 to 128 mils, although copper-steel, bronze, or steel conductors of similar diameters may be used for additional strength in longer spans. For 100- to 200-ft spans, which are normally used in communication lines, the *parabolic* formula is used in computing sags and tensions, in place of the more complicated *catenary* formula.[6] Common practice for effecting transpositions, particularly at the higher frequencies, is to employ point-type transposition brackets mounted on crossarms, or in long spans to use span brackets supported by the wires themselves (Sec. 17).

In urban localities, or where the number of circuits required is too large to make open-wire construction practicable, multipair cables, either paper-insulated and lead-sheathed or plastic-insulated and sheathed, are installed either aerially on poles[7] or, where congested conditions aboveground prohibit the use of aerial plants, underground.

Conductor sizes in such telegraph cables vary from 16 to 22 AWG. The number of No. 22 conductors may exceed 1,600 in a cable that is 2⅝ in. in over-all diameter.

Transmission losses in cables vary inversely with conductor diameter. Since even 16-gage conductors have considerably higher losses than open wires, inductive loading must often be resorted to and repeaters must be spaced closer than with open-wire circuits. At junctions of open wire and cable, it is necessary to provide impedance matching for carrier.

Lead-sheathed paper-insulated cables are terminated by splicing them either to the stub cables of gastight sealed terminals or to lead-sheathed rubber or textile-insulated tipping cables, the individual conductors of which are terminated on connecting blocks. Where tipping cables are used, a dam consisting of a suitable wax or resin[8] is provided in the paper cable to make it gastight and thereby prevent moisture from being drawn in by breathing action of the cable due to changes in temperature. Plastic-insulated cables require neither gastight terminals nor tipping cables, since their insulation is relatively impervious to moisture.

Nitrogen introduced into lead-sheathed cables at pressure from 12 to 15 psi is used to locate sheath defects by either pressure gradients, differential-pressure changes, or changes in direction of gas flow. After sheath faults are localized definite locations

are determined with a soap solution or, in the case of major defects, by the sound of escaping gas. The cable is sectionalized by dams inserted at intervals of from 1 to 2 miles before introducing the gas. Important cables are maintained under gas pressure and provided with low-pressure alarms. Alarm gages have a high and low setting; the length of time between the first alarm and the second indicates the magnitude of the leak.[1]

Telegraph cable installed on pole lines is supported by high-strength galvanized or stainless-steel strand, bolted to the poles. The cable is attached to the supporting strand by metal rings or hangers or by corrosion-resistant wires spun spirally about both strand and cable.

26. Underground Cable and Duct. Where cables are placed underground they are either pulled into ducts of vitrified clay, asbestos cement, or fiber or buried directly in the ground. For direct burial, lead-sheathed cables are usually protected with jute and steel-tape armor, while plastic cables are provided with an additional plastic sheath. Manholes are provided at intervals of several hundred feet in duct runs to facilitate installation, testing, and maintenance of the cable.

Lead-sheathed cables installed underground are subject to electrolysis and other forms of electrochemical action due to stray currents and varying earth potentials along the run; so surveys and frequently drainage, cathodic protective systems, or other mitigative measures are necessary to prevent the lead from being destroyed.[2]

TELEGRAPH SYSTEMS

27. Information Theory. Under this title (*cf.* Chap. 1, Sec. 46) are grouped the principles relating to the efficient and accurate transfer of intelligence, discrete bit by bit, from mind to mind. Principles concerning so much of that transfer as may be accomplished by electromechanical means from place to place are sometimes given the narrower title of *communication theory.* The word "modern" is sometimes used to underline the fact that the generalizations and formulas used are recent, though efficiency of codification and the elimination of transmission redundancies are old to the narrow-band telegraph art. Morse code (in its allotment of short, dot-dash combinations) and the American version of Baudot code (in assignment of its one- and two-pulse characters) both bear internal evidence of studied correlation of the briefest code symbols with the highest probability of letter occurrences. Optimum correlations may now be formulated by means of the theories of probability and statistics[3] based upon analogies in thermodynamics[4] and leading to the formulation of ideas of recognition of and choice among messages (aggregations of informational bits) against a background of interference, or noise.[5]

These precepts of communication theory have directed attention to the avoidance of *on-line* transmission redundancies by the expedient of incorporating (*cf.* Sec. 28) qualities of *memory, anticipation,* and *prediction* into receiving equipment.[6] Even more significantly, basic relationships have been demonstrated[7] to exist among signal and noise power, band width, and capacity of a circuit to handle information, which, by raising questions as to ways in which each of these factors may be manipulated for

the benefit of the others,[1] may influence future telegraph-system designs. The discovered relationship is that the upper limit of the amount of information C measured in binary units (bits) per second, which ideally can be transmitted in one direction over a transmission system in the presence of Gaussian white noise of average power N, is related to the average received power P in the signal and to the band width W occupied by the system expressed in cycles per second according to the equation

$$\frac{C}{W} = \log_2\left(\frac{P+N}{N}\right)$$

Among variants[2] of this relationship are

$$C_1 < W\log_2\left(1+\frac{P}{N}\right) \qquad \frac{C}{W} = 3.3\log_{10}\left(1+\frac{P}{N}\right)$$

$$C = W\log_2\left(k^2\frac{P+N}{N}\right) \qquad C = \frac{H}{T} \leqq 2W\log_2\left(1+\frac{S}{N_v}\right)$$

in which C_1 is *practical* informational capacity rather than ideal; $k \leqq 1$ is a constant defining a desired *quality* of transmission; H is the number of bits in a message and T the number of seconds required to transmit it; S and N_v are, respectively, the *rms* voltages of *maximum* signal and average noise.

Fig. 12. Signals in two-level code A at frequency f and power P are replaceable by equivalent four-level code B at frequency $f/2$ and power $4P$. The intelligence communicated C is the same: bandwidth W has been narrowed by increasing power P, noise N remaining constant. (*From R. M. Page, Comparative Study of Modulation Methods, Trans. IRE*, **CS-1,** *p.* 13, *July*, 1953.)

The basic formula is useful in comparing a given communication system with the ideal and in comparing two systems whose parameters are not greatly different. It will be noted that a low N/P ratio contributes greatly, as a design objective, to the traffic capacity of a telegraph system which has to operate within a limited band width. Conversely, in other instances it may be advantageous to employ wider bands to reduce power.

Each of the factors in the equation is subject to searching reexamination in the light of their relationship. Thus P is not to be considered merely as total power but as composed of *discrete quantized levels* available for the handling of new and more efficient codification of information. From Fig. 12 it will be evident that a direct trade may be made between band width and the number of levels employed in codification.

The end product of communication C is also to be scrutinized in the light of new machinery to handle it—to put it down on paper or to feed it into terminal equipment for the direct operation or control of other machines.

[2] Page, R. M., Comparative Study of Modulation Methods, *Trans. IRE*, **CS-1** (1), 13, July, 1953. Anon. (Netherlands), CCIR Document 348-E, VIII Plenary, Warsaw, 1956.

Band width W comes under scrutiny for its present stratification by frequency guard-band losses, and questions are raised as to what extent spectrum space can be conserved by more general use of time-division multiplexes, of types freed by electronics from mechanical limitations.

Especially is C to be examined from the viewpoint of transmission redundancies, raising questions of how much detailed information must be transmitted over circuits and how much can be stored in receivers for use at the behest of control information signals received.

The English language itself, containing countless redundancies and statistical relationships of recurrence frequencies of single letters, diphthongs, digraphs, trigraphs, words, and word sequences, well known to cryptologists,[1] is subject to reexamination in the light of the task of teleprinters to reproduce it. Instead of dealing with one letter at a time, telegraphy may concern itself in the future with the historicity of the pulse sequences transmitted, to ascertain whether they contain statistical properties of movement that can be built into transmitters and receivers, alike, so that only a residue beyond the momentum of each sequence occupies band width in transmission.[2]

By use of storing and searching techniques now commonly built into computers, advantage may be taken of what telegraph transmitters and printers can be made to learn and remember about the sequence of letters in any language. From this advanced viewpoint, a uniform five-unit mark-space code now used in teleprinters is unnecessarily long in that, after each letter is printed, it insists on reserving needlessly a full measure of spectrum for the reception of the next letter. This is not only because the infrequent letter Z and the frequent letter E each contain five pulses, but because, having transmitted in succession a *word space* and the letter Q, present systems assign a full five units (instead of, ideally, one unit or *no* unit) to the letter U which is almost certain to follow.

Suggestions have therefore been made[3] that telegraphy, like television, experiment in new ways to codify intelligence: dealing perhaps not in single letters but in digraph and trigraph sequences; reserving the longest code groups for the greatest departures from normality, and very short groups for normal sequences; telescoping the information at the transmitter; signaling the departures from normal, leaving it up to the receiver to fill in the normals; at the receiver expanding information while decoding it, thus saving band width on the line.

The new approaches therefore trade simplicity of terminal equipment for transmission-spectrum savings. Economics and scarcities are seen to be fundamentals governing research in this field.

The urge to conserve band width by code economics or otherwise varies widely with types of circuit. For local tie lines, where conductor pairs cost as much for teleprinter speeds of 23 cps as for full v-f bands, there is little incentive to compress more information into fewer bits—in fact it has been found advantageous to adopt facsimile, occupying the full band, for certain collateral advantages over teleprinters. But on intercity and international telegraph circuits economics bars the widespread use of wider band widths than are essential to convey information, and here the utility of an extremely short code (approaching two pulses per letter with two-level power[4]) shares interest with more efficient employment of spectrum by multiplexing.

28. Signal Levels and Codes. Facsimile telegraphy, telephoto transmission, and television utilize smooth transitions within a spectrum of gray values between black and white. It has been shown that 128 quantized signal levels may be controlled by a seven-unit code using pulse-position modulation,[5] wherever signal-noise ratios are suitable.

For reasons summed up in the description of distortion (Sec. 18) and epitomized by remarks under teleprinter operating range (Sec. 19), most land-line telegraphy is conducted today on a two-level, polar, or f-m basis. Three levels are successfully used in cable Morse where a low level of interference does not preclude one level's being at earth potential. Four levels were, in effect, employed for many years in the land-line quadruplex, wherein a reversal of polarity and a current increment were used for independent signaling.[1]

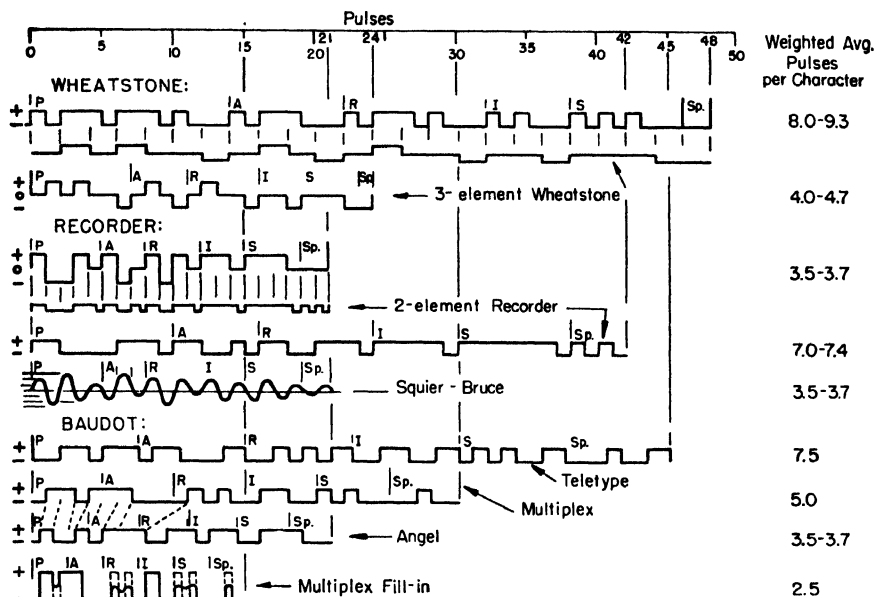
The 6-*level Squier-Bruce* code of Fig. 13 deserves mention for its beguiling resemblance to a.c.[2] It is an adaptation of Morse, using an arbitrary reversal of polarity


FIG. 13. Comparison of lengths of codes. The first figure is for the "average word" *PARIS* followed by a word-space; the second is for average telegrams in English, including preambles (headings). The codes are described in text. (See also Coggeshall, I. S., *Trans. IRE*, **CS-1**, 4, July, 1953, or *WUTR*, **7**, 56, 1953.)

between successive signals on three levels, dashes taking the maximum applied sine-wave emf, word spaces the minimum, and dots the median level. One of the shortest codes, its wave form resembles a carrier whose frequency exactly coincides with the frequency of intelligence modulation. Its successful transmission would necessitate solution of power-noise relationships at all rms levels, overlapping of side bands, and the suppression of transients inherent in the permutation of signals among six potential levels; the problems resemble those encountered in diplexing f.m. on a.m.

The *Cooke three-unit* code called for three-level transmission, yielding only $3^3 = 27$ combinations, three of which had to be allotted to word-space and carriage shifting, forcing two little-used letters into the upper case.[3] A *four-unit three-level* code would yield 81 combinations—a practical challenge to designers wishing to break with mark-space tradition by adding the third potential level.

Figure 13 shows how the British cable system adapts *two-level Wheatstone (Boehme)* Morse for three-level transmission, with a halving of bits per letter.[1] The system is based on the observation that machine-perforated Morse tape, unlike Baudot, contains only three pairs of binaries: M-M, S-S, and M-S (S-M being lacking). The conversion of code levels is accomplished at repeaters where cables (safe for three-level transmission) and land lines (with their distortion problems) meet. Figure 13 also

[a] The nominal transmitting speed may vary by not more than 1 per cent because of compromises in gear ratios made by various manufacturers.

[b] The nominal pulse lengths may vary by not more than 1 per cent because of compromises in gear ratios and rounding off of angles between transmitting cams or the included angles of faceplate segments. Actual pulse lengths may vary by as much as 3 per cent when signals are generated by a faceplate type of distributor or distributor-transmitter, and by as much as 5 per cent when signals are generated by cam-operated contacts, as on a keyboard transmitter.

[c] An "average" word is considered to be six characters long, including the space following the word and any function characters transmitted, such as letters shift or figures shift.

[d] These two codes are compatible.

[e] 7.42-unit equivalent frequently referred to informally as "seven and a half' unit codes.

[f] 368 o.p.m. is frequently referred to informally as "60" words per minute, or "60-speed."

[g] These three codes are compatible.

[h] 460 o.p.m. is frequently referred to informally as "75" words per minute.

[i] 7.42 equivalent employed by all United States users at 460 and 600 o.p.m.

shows how the reverse takes place in the use of the *Higgitt* code in lengthening cable-recorder Morse to two levels when passing from cables to radio or land lines.

The uniform-length *two-level five-unit teleprinter* code[2] (see Chap. 24, Secs. 3 to 13) used in radiotelegraphy is in practically universal use in wire operations. Figure 13 affords a comparison of its length—in its multiplex, start-stop, and submarine-cable versions—with other wire-telegraph codes. Only in its time-division-multiplex application (Sec. 36) does it perform its whole function with five transmitted units; its

employment with addenda of start and rest pulses of various lengths is shown in Table 4, together with data relating to the printers using five-unit code (Baudot). Its $2^5 = 32$ possible combinations are distributed among 26 alphabetic letters and 6 printer manipulating functions, chief among which are the two which change the printer case to introduce 10 numerals, punctuation, and additional control signals. Two of the latter controls could, of course, put a modified printer into third case with the same code, and such machines have been built experimentally. An analogous more practical extension of the five-unit code's capabilities is employed in the *stunt* mechanisms of modern printers.

Six-unit general-purpose printers have been proposed to afford $2^6 = 64$ combinations, making possible easy adaptation of printers to the typewriter's lower-case type font, or giving scope to language alphabets containing more than 26 characters as commonly printed. *Teletypesetters*[1] fall in the six-unit category. A growing number of accounting,[2] inventory,[3] computing,[4] and other business machines require more than five units (Sec. 37).

Stock and commodity printers use a six-unit modification of five-unit Baudot code, adopted because of the occurrence of many shifts to upper case in ticker tape. The presence or absence of the sixth unit of the code determines the case in which the Baudot-selected character will print.

By allotting to the most frequently used letters in English the minimum number of marking pulses, Baudot code saves wear and tear on machines and reduces the average number of polar signal transitions on the line per character handled on start-stop machines to two,[5] thus aiding accuracy. *Angel's* shortened version[6] of Baudot was successfully used on submarine cables. The marking bits of Baudot were transmitted at ordinary length and frequency, but there was an arbitrary reversal of polarity between successive marking pulses. The spacing impulses were transmitted half length each, any number of them in succession being joined as to polarity with the marking impulse which preceded them. The characteristic uniform length of Baudot characters was sacrificed. Angel's choice of *mark*, rather than *space*, for full-length transmission conformed with the Baudot code's correlation of the fewest mark bits per character with the most frequently used characters.

FIG. 14. Gulstadt fill-in circuit. Original transmission as in *C*. Nearly attenuated single impulses and fully transmitted doubles (and more), after transmitting line, shown in *A*. In *B*, singles have been fully suppressed by amplifier shaping; in *C* they have been locally filled in, thus wholly restored.

Modern ocean-cable transmission utilizes a *Gulstadt vibrating fill-in* circuit[7] which multiplies by a factor of 1.8 the traffic-carrying capacity of unmodified Baudot. Its effect in contracting code length is depicted on the last line of Fig. 13. The system calls for the transmission of ordinary five-unit tape at a rate so high that single bits are almost attenuated,[8] as shown in Fig. 14*A*. The noise level in the cable associated with single bits becomes no longer a factor in their reception; the materiality of noise N may thereafter be related to the signal power P included in lobes composed of *two*

bits, to which the receiver circuits are resonated with the effect shown on line *B*. The attenuated single bits are then interpolated locally by flat-top a.c. generated by an auxiliary ring on the distributor, restoring, as shown on line *C*, the original shape of the signal train including all the single bits. The system takes advantage of the filtering action of a long cable, worked to the maximum traffic capacity its band width will permit, in suppressing information which the receiver can predict—in this instance that, upon decay of a bit or a succession of like bits, the next bit will be of opposite polarity whether or not strong enough to be sensed by the receiver.

29. Wire and Radio Systems. Morse and teleprinter codes, described in Chap. 24 as used on radiotelegraph circuits, are used on wire-telegraph systems. The importance of Morse has sharply declined in American land-line and submarine-cable practice. Its present chief uses are in connection with regulating American circuits in cases where the telephone is not used, in the world-wide British cable system, and on various European lines.

Teleprinters or teletypewriters, under the trade names of Teletype, Creed, Siemens & Halske, Olivetti, and others, are in almost universal use in the United States and are widely used in Europe. The majority of them operate on start-stop synchronism as typified by the type 15 Teletype and the compatible[1] Western Union start-stop teleprinter, the differences between which are shown in Table 4. Distributor-transmitter adjuncts,[2] operating "off-line" from prepared five-unit tape instead of directly from the "on-line" keyboard, are in general use wherever it is expedient to reduce to zero the line time lost by slow manipulation or imperfect keyboard cadence, or wherever it is desired to precheck transmission initiation accuracy.

It is the practice to operate teleprinters in country-wide end-to-end circuit connections over telegraph carrier facilities of both the telegraph and telephone companies. Beam, microwave, and scatter-beam radio links are used in certain cases where expedient and economic. Radiotelegraph and submarine-cable links overseas also interconnect American and European teleprinters.[3] Keyboard-typebar-code standards, based upon international alphabet No. 2, apply alike to European and American land-line and overseas practice. To accommodate alphabet differences among the various languages, the standards have to provide for certain choices, easy to arrive at by agreement between any two countries but presenting more difficulty when two continents are involved. The differences, which are being eliminated or accommodated by automatic *code translators*, are more acute as to "stunt functions" of teleprinters and to punctuation than to alphabets and numerals. The European speed standard (50 bauds; *cf.* Table 4) and its 20-millisec pulse length compared with 45.5 bauds and 22 millisec in the United States also require specialized repeaters to reconcile.

Telegraph circuits may be classified in two ways: those which are more or less permanently set up between terminals (*trunks*) and intermediate (*way*) stations (*drops*), and those which are usually made up of component line sections temporarily joined by switching. Switched circuits may again be classified in two ways: those which are made up of line sections closely coupled by direct connection or repeaters; those whose line sections are more loosely coupled by reperforators (tape storage), magnetic drums (memory devices), or variants. Both permanent and switched circuits may be one-way, two-way for simultaneous operation (duplex), or two-way back-and-forth (half-duplex).

Both the radio and the wire companies lease their facilities to governmental and commercial users for private-wire services. These are almost universally teleprinter circuits, the simpler installations consisting of two printers and a two-way "line," working one way at a time (half-duplex) or both ways simultaneously (duplex).

With the multiplication of outlets, private networks are frequently developed, with provision for switching and storage.

The telephone companies in the United States furnish switched telegraph interconnections for TWX subscribers by means of teletypewriter exchange service, employing many of the switching methods and devices applicable to long-distance telephone calls.[1] A similar network of the various telegraph administrations covers Europe under the name "Telex." The American radio companies furnish overseas connections between TWX and Telex.

Public telegram service is furnished abroad by post office authorities who also administer telephone service. In the United States the telegraph company renders the message service,[2] employing its own facilities and those it leases from the telephone companies. The use of telegraph carrier to subdivide owned or leased voice bands is typical for intercity connections. Interconnected major reperforator switching centers are located strategically to serve all other telegraph points in their territories as tributary offices. Reperforator offices are by-passed in certain cases where community of telegraph interest between two cities calls for direct trunk circuits. Microwave radiotelegraph is employed on selected trunk routes of high traffic density justifying the capital expense.

Radiotelegraph companies have established central offices in international gateway cities for handling overseas the same types of service in similar fashion, using similar land-line circuits and equipment.

Problems associated with connections to branch offices, subservient to central telegraph offices in a given large city, and with telegraph connections of the land-line, radio, and submarine-cable common carriers to their customers[3] absorb a great deal of administrative and engineering thought but are considered beyond the scope of this handbook except for the treatment of *loops* and *legs* (Sec. 31). Such terminal handlings are usually accomplished by teleprinter *tie lines*, *facsimile* tie lines, by the public telephone service or special telephone tie lines, by underground pneumatic tubes,[4] or by foot, mounted, or automobile messengers. Of these methods, facsimile transmission is the fastest growing for the purpose stated, teleprinter the one most compatible with intercity transmission and the only one widely employed by the telephone companies.[5]

30. Start-Stop Teleprinter Systems (see Chap. 24, Sec. 18). The simplest system, say for intraplant dispatches, consists of two compatible a-c- or d-c-powered teleprinters in the same locality working together alternately back and forth over a grounded line or metallic loop. The line, supplied with d.c. or rectified a.c., will stand normally closed on the rest (stop) segments in the printers. Speed matching is unnecessary so long as both printers are a-c driven from a 60-cps supply source; d-c machines will require a simple stroboscopic speed adjustment, checked with a portable tuning fork. Operating *margin,* or range, measurement and adjustment are built in. Electrical protection must be provided. Supervisory alarms and printer-control signals operable upon initiation and termination of calls or faulty line conditions are optional. A system of exchange of serial-message-number information guards against line and operator failures.

Apart from make of teleprinters selected, a choice must be made as to whether they are to constitute a *page*-producing or a *tape*-producing system. Printer tape is gummed on the back and affixed with a hand-held moistener. Tape operation facilitates neat correction of most errors by a paste-over technique, with consequent economic advantage. Page printers for use in their own offices have more appeal to business users[1] and are more versatile in such business tasks as preparing carbon copies and forms. Since keyboard and type-pallet associations with the Baudot code differ as between page and tape printers, the two types are incompatible in a system unless end-of-line attachments are placed on keyboards and complex code translators are placed ahead of printers.

Choice of printer speeds will ordinarily fall among those most in use, nominally 60, 65, 75, and 100 wpm. The 75-speed lies on the outer margin of continuous operational ability of a typist capable of producing 100 to 125 wpm in spurts on a typewriter. However, distributor-transmitters may be procured which, even more effectively than any operator, will occupy full line time at 75- and 100-speeds. Choice of speed is an economic balance between traffic-load totals, traffic-peak requirements in each direction, expected average and maximum speed of service required, distance between terminals, line-rental rates, equipment-rental rates, and operators' and maintainers' salaries allocable to the telegraph operations. Marginal situations sometimes control choice of whether to pay for premium speed, adopt full-duplex instead of half-duplex, or add another circuit.

The teleprinter is normally operated as an entity, the machine at each end of the circuit printing, in turn, a home copy of its own sending, then copy received from the distant end. However, the keyboard and typing mechanism may be split, at will, for duplexing the line (two ways simultaneously). In that event the home copy is suppressed, and the operator sends blind; meanwhile the typing mechanism remains responsive to signals from the distant end. If home copy is desired, two machines are used at each end of a duplexed circuit.

For more typical operation between different localities, a user will secure lines from the telephone or telegraph common carriers; both compete for the business and include engineering counsel as part of their service; the same observation would include the radiotelegraph companies for service overseas. Customers' teleprinters and associated tie-line loops, including power-supply devices, are usually recommended by the carrier and furnished on a rental basis; in today's practice they actuate intercity carrier modulators in the companies' central offices.

31. Loops and Tie Lines. Teleprinters, as either sending or receiving instrumentalities, are usually connected with central telegraph offices by subscribers' loops (two conductors in cable) or legs (single conductors). At the central office the loop or leg works through either a repeater or relay or directly to actuate an intercity channel, neutral, polar, or carrier.[2] The availability of power on the subscriber's premises sometimes determines the type of loop or leg operation adopted. A-c lines will supply the teleprinter motor, but if loop or leg arrangements make it necessary to supply neutral or polar d.c., it must usually be obtained through use of rectifiers.

The advantages accruing to polar main-line operation (Sec. 14) carry over to leg operation. A case can be made for universal use of polar legs and loops;[3] a trend in that direction has been facilitated by the availability of cheaper sources of rectified polar potentials and simpler polar relays; and further impetus will be lent by the fact that the new 28-type printer is polar-equipped. For regulating facility it is desirable to have all legs converted to polar operation if any are.[4] At present the 15-type tele-

printer requires a supplementary relay for polar operation. Certain carrier channel legs are worked without relays,[1] simple closing and opening of a loop by the subscriber having the effect of using central-office d-c battery to shift the carrier frequency; but polar loop operation may be used if desired (Fig. 17).

In Bell System practice[2] f-m carriers are manipulated over d-c on-off loops in cable for as long as 25 miles without need of correcting any loop-signal distortion.[3]

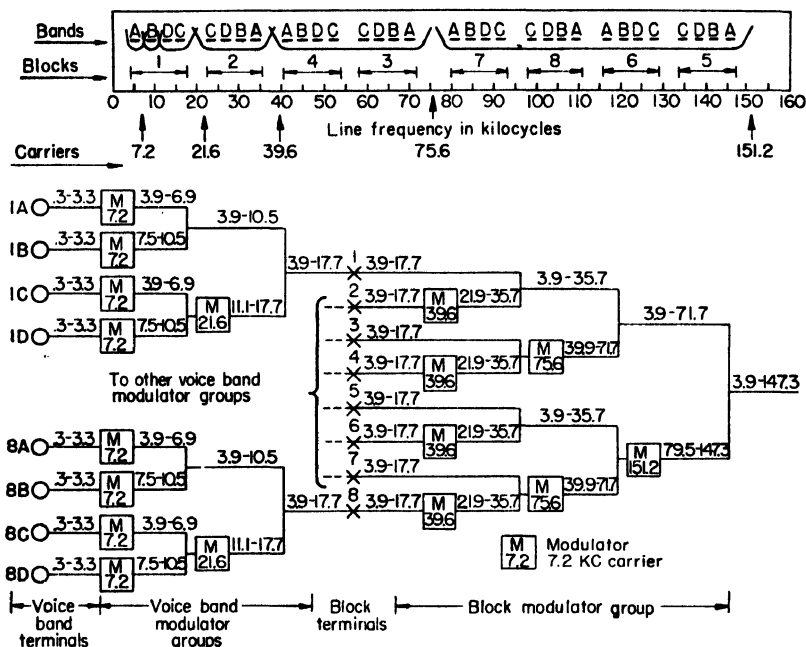
32. Telegraph Carrier Systems. Typical modern wire-telegraph transmission between cities is accomplished by amplitude[4] or frequency modulation[5] of continuously


FIG. 15. Frequency allocations in one direction in a 150-kc telegraph system. All v-f channels in all eight blocks are shown in the spectrum layout. The modulator layout shows only the outer blocks, 1 and 8. There are 16 teleprinter channels in each v-f band. The number of v-f translations each undergoes varies from five (in 8C or 8D) down to one (in 1A and 1B); there is an additional translation for channels in each upper subband of v.f.

generated a-f carrier channels, stacked above each other by processes of frequency-division multiplexing and frequency translation to fill the available spectrum of the wire circuit, as shown in Fig. 15.

The 3-kc v-f band is the vehicle of all present-day long-haul telegraphy. When carried along with voice bands in use for telephonic conversations on the telephone companies' wires, the center spacing of v-f bands is 4 kc. Each v-f band is broken down in telegraph-company practice to two subbands and each subband into 9 channels with centers 150 cps apart. In American telephone practice the separation of center frequencies for telegraphy is 170 cps; in British Post Office practice, 120 cps.

[5] Bramhall, F. B., and L. A. Smith, A Nation-wide F-m Telegraph Network, *Trans. AIEE*, **70,** 338, 1951.

The Bell System's a-m system subdivides a v-f band into 20 telegraph channels; its f-m system[1] provides as many as 17 telegraph channels in the v-f range.[2]

It will be appreciated that in carrier telegraphy several scores of telegrams are being handled simultaneously over the same unidirectional pair of conductors, often in association with telephone, telephoto, and other modulations being applied at the same time. Nevertheless, each unit impulse of each letter of each telegram imparts its influence to the wave shape of the composite applied emf; and the line, filters, and other common apparatus respond accordingly. The designer has a choice of whether to employ a-m or f-m type of modulation for signaling on the individual telegraph channels.

FIG. 16. F-m telegraph signals in sending oscillator (D) and at receiver before limiting (G), showing influence of sidebands on receiving amplitude.

By use of f.m., freedom is secured from errors due to changes in transmission equivalent on the vehicle channels and from errors due to extraneous disturbances, equivalent to about 9 db, from all sources;[3] and by taking advantage of f.m.'s equal-valued signal strengths of different frequencies, the telegraph system works, as in polar operation, independently of the magnitude of the incoming envelope of the carrier compared with a local reference level, and free of mark-space bias.

On each a-m frequency-division channel of communication the carrier or a subcarrier has its form altered by the modulation frequency and supplemental power

added to it by pairs of modulation side frequencies.[1] Similarly, f.m. influences the form of carrier as shown in Fig. 16. The carried wave C varies the instantaneous frequency of carrier A. Close examination of the line wave D will show employment of unity modulation index, the carried wave being 35 cps for teleprinter operation[2] with 150-cps spacing between adjacent channels, and the line wave being deviated 35 cps either side of its unmodulated frequency. Since the carrier wave in f.m. is not furnished supplemental power by the side bands E and F, the side-band power is contributed by the carrier as shown in G; the second- and third-order side bands which constitute less than 3 per cent of line wave power are eliminated in practice.[3]

The channel transducer which converts transmitting loop d-c signals into corresponding channel frequency modulation is shown in Fig. 17. The rated output power of the oscillator-amplifier is 10 dbm. Transients in the tuned oscillator circuit, due to sudden transition of the telegraph impulse which might persist even longer than the
FIG. 17. Modulation of f-m telegraph carrier channel by leg or loop from subscriber. No relays are required.

duration of the transition interval, are overcome by the circuit configuration represented by the differential transformer, the split inductor, and the twin diode. C_1 remains in circuit at all times; C_2 is cut in and out of the tank circuit in response to keying of the loop circuit. With the sending loop open it draws no current and the potential of A is 20 volts positive with respect to B. The diode is conductive and acts to cut C_2 out of the tank circuit. L_1, L_2, C_1 are proportioned to produce the spacing frequency. When the sending loop is closed, a drop of 40 volts in R_1 causes A to become 20 volts negative with respect to B; the diode becomes nonconducting; C_2 is switched into the tank to lower the oscillator frequency. The marking frequency f_m is just 70 cps below f_s. The shift is rather abrupt but as observed at the output of the sending-end channel filter is gradual as dictated by the band width of the filter and the reluctance of its "frequency time constant" to accommodate a shift in frequency. As a result, looked at from the receiving end before limiting, the frequency change is practically sinusoidal, just completing one transit in time to start the next (Fig. 16).[4]

Such a channel, centered, say, on 825 cps and deviated ± 35 cps, will accommodate, on a nationwide basis, 100-speed start-stop channels (75 bps, 37.5 cps) if desired; on a more restricted basis certain of them are carrying three-channel time-division-multi-

plex printer circuits at a total speed of 200 wpm (100 bps, 50 cps). Its ordinary loading consists of a one-way 23-cps teleprinter. Eight companion channels, with eight pairs of generated f-m values, share with it a subband, shown in Fig. 18.
FIG. 18. Channel allocations in primary sub-v-f band. Separation between centers, 150 cps.

A complete small carrier system could be so devised, and, as a matter of fact, in telegraph-company practice, even when larger ones are compounded of stacks of such half v-f bands, only these nine pairs of frequencies are generated by the oscillators. In the telephone company's a-m practice, where 20 telegraph channels occupy a v-f band, the 20 are separately generated.

In either case, the generated groups are stacked, or translated upward into their proper individual occupancies of the upper parts of the transmission spectrum,[1] by double-balanced modulators,[2] and at the receiving terminal inversely demodulated to produce the original basic f-m channel signals for detection, discrimination, and printing.

In Western Union practice,[3] two nine-channel subbands are placed together, by translating one of them, to form a v-f band (Fig. 19). In its use of Bell System carrier facilities, Western Union modulates each v-f band in this way. Alternatively, when it uses its own lines, four v-f bands are stacked to form a block, and two blocks will constitute a 30-kc carrier system. Or four blocks may be stacked to constitute a block modulator group; and two of these groups, comprising 64 subbands, compose the 150-kc SSB suppressed carrier system,[4] with $P/N = 53$ db. In Fig. 20, one such 150-kc system is shown as f-m modulator of 1,000-kc f-m subcarrier of an r-f micro-wave-beam carrier in the 3,900- to 4,200-Mc band, deviated ± 2 Mc.[5]
FIG. 19. Translation of v-f subband to fill voice band. Primary modulated subband is that of Fig. 18. Modulation with the translating carrier produces primed telegraph channels in second subband. Entire v-f band becomes building block for further translations of Fig. 15.

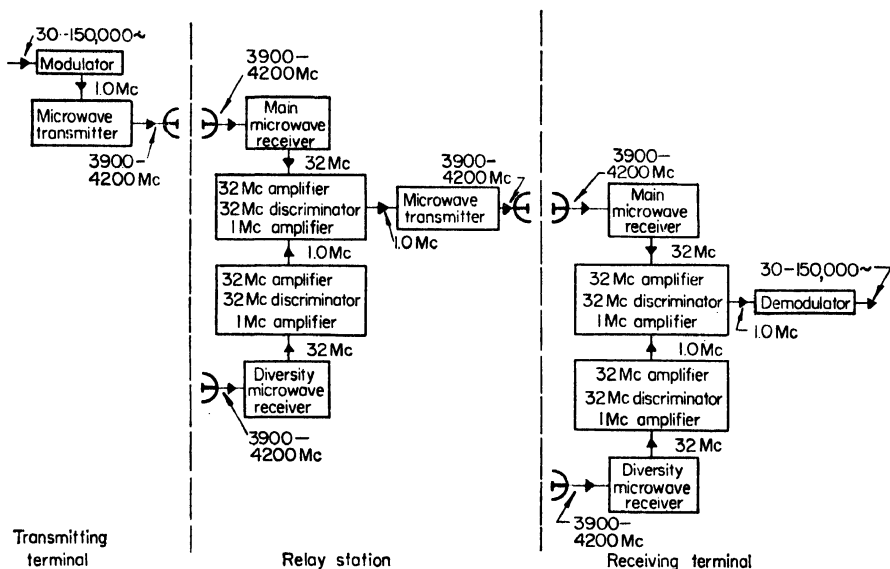
33. Switching and Storage Systems. Reperforators—receivers which differ from printers in that they re-create punched tape to be run for onward retransmission rather than page "copy" or gummed typescript tape—have found wide application in connection with the temporary storage of telegraphic information and its switching, either manually or automatically, to other circuits. Typical reperforators (Sec. 44) reproduce at a distance perforated five-unit Baudot tape, although designs using six-unit *uniform-length code* and Wheatstone (Boehme) Morse nonuniform code are in widespread use. The number of unit signals across a tape and the number of center holes (for transmitter-feed purposes) per character may vary as required up to mechanical limitations. Sensing of coded punched holes is usually accomplished by the introduction of transmitter pins which actuate contacts, although photoelectric


FIG. 20. One 150-kc (32 v-f) band of Fig. 15 applied to microwave beam. Double f-m modulation is employed to translate broad-band telegraph spectrum through 1 Mc to 4,000 Mc at transmitters and through 32 Mc and 1 Mc at receivers. One repeater station is shown. Space-diversity reception is employed.

means afford an alternative. For higher speeds, magnetic tape and drum storage and xerographic[1] processes are being experimentally employed.

Reperforators are ordinarily organized into switching systems in which their characteristic function is the temporary storage of information at junction points in a chain of circuits. Such loose coupling lends itself to one-way operation of telegraphs, with economic advantages flowing from: (1) relief from the necessity of setting up a circuit route all the way from point of origin to destination of a telegram in order to avoid manual retransmissions en route, (2) consequent widespread interchange utility of circuit sections, (3) reduction in holding time in channel-mile-minutes, and (4) reduction of idle time on that half of a two-way circuit held inoperative in back-and-forth working. Reflecting these economies, the reperforator has radically changed the physical

aspect of central telegraph offices, land line, cable, and radio alike, and has been the prototype for other information-storage devices, such as those used in computers and card-punch business machines.

The versatility of reperforation, as a system, for serving commercial telegram, private leased telegraph wire, and teletypewriter exchange services has been due in large measure to the highly developed switching techniques[1] of telephony (*cf.* Chap. 28, Secs. 14 to 19). Pulse-controlled and relay-operated ringing, signaling, and supervisory systems by which telephone voice circuits were at first manually established by operators and later set up by dial-operated machine switching constituted the first widespread intercity use of nonlanguage "data," or bit-by-bit information (Sec. 37).

In telegraphy as in telephony, the principal switching components are two-position multicontact relays and rotary and crossbar switches. Transmission accomplishes their accurate positioning, often at high speed, by sequences of binary bits, through whose means a traffic route (often a preferred route) is set up over available wire facilities from origin to destination. Parts of the switching circuits which set it up withdraw for like service on other calls. Other parts of the plant supervise the connection, often make prearranged interpolations or excisions of transmitted information, and at a proper time pull the circuit down, redistribute its portions and apparatus for subsequent use, and make records upon which to bill for services rendered.

As in the parallel case of dial telephony, the switching sequences are directly initiated by the sender (calling subscriber).[2] He may employ a push-button, dial, or teleprinter keyboard. Dials are employed on some European telegraph networks. Two-character director (selector) signals originated from teleprinter keyboards are the preferred fully automatic form in network telegraphy in the United States although ordinary push-button or supervisory key signals often suffice to bring in a central-office telegraph operator on a subscriber's call. Control of the starting and stopping of the motor in the customer's teleprinter by the central-office operator is often employed as a reverse signaling and control device in the initiation of telegram transmission.

By *director signals* supplied either by the patron or by the switching operator, the telegram is taken into tape reperforator storage or transmitted to destination. A second set of director signals may be employed to indicate priority handling, in which event they will activate a path to reperforator storage and deferment of subordinated messages, or to designate a special disposition of the message within the reperforator system.

The second vital element of control is the *knock-down* or *end-of-message indicator*, universally supplied from the teleprinter keyboard, which causes circuits to be restored to nonuse normal, either directly or through supervisory-cord signals. Together, the director and end-of-message signals mark transmissions off into message units, each one of which in sequence may be headed toward a different destination.

Taking tape into temporary storage affords the slight time delays which permit characters to be interpolated or extracted in response to other switching controls. For example, strings of messages from two circuits may be interleaved (flip flop) into one circuit under control of selector and knock-down circuits. Or a tape may pause, under control, to pick up a sequence number from a cam-driven automatic numbering machine. A director signal, having utilized its effectiveness in throwing a switching sequence into operation, may be reintroduced in an initial position for rereading at the next reperforator point (cross office or otherwise).[3] The time of day (A.M. or P.M.) may be introduced into the transmission from a coding device geared to a timepiece.[4] A translator may be interposed to change certain characters into different ones to render the sending keyboard compatible with the receiving teleprinter. Or tape may

be edited under scrutiny and stopped for manual correction for one reason or another. Other examples will be found in connection with treatment of private-wire systems.

Since incoming and outgoing circuits usually operate at the same normal speeds, it is evident that, if any pause in transmission, however slight, is to take place within a reperforator office, the cross-office facilities there must operate at higher than normal speeds if a gradually increasing accumulation of unsent tape is to be avoided. This leads to *double reperforation* and completely loose coupling between incoming and outgoing circuits. The cross-office linkage is supplied by rotary switches[1] or crossbar switches,[2] actuated by reading and sequencing circuits or by manual push-button control.

In a reperforator office which is neither fully automatic nor semiautomatic (push-button-operated), the loose coupling between incoming and outgoing circuits is accomplished by tearing the incoming tapes between message units and manually feeding them, in proper sequence, into transmitters connected to outgoing circuits.

Timing circuits and slow-acting relays find considerable use for circuit supervisory purposes,[3] either to initiate alarms or to take direct action when, after a measured interval, some expected sequence fails to take place (usually through human delay or error) or some required choice has not been finalized.

Reading (director) circuits, involving relay trains wired to disclose the occurrence of given character combinations in the transmission, are used to initiate switching functions.

Sequence circuits[4] are arranged to take note of incoming events (like first-come first-served) or the switching requirements or limitations of outgoing facilities (such as a limited number of trunks), and to sequence the switching in accordance with formula.

Telegraphy has benefited from and contributed to recent progress in information handling by digital computers. The switching specialist treats his plug, jack, key, multipoint relay, multiterminal switch, diode, rectifier, varistor, and transistor problems of mechanizing intelligence by methods of switching logic, switching algebra, and a descriptive geometry. He uses simple but versatile two-valued circuits which sense, find, count,[5] read, accept, reject, hold, lock out, collect, memorize, repeat, compare, check, correct, translate, choose, compute, hunt, test, select, operate, control, transfer,[6] connect, separate, time, record, restore, disconnect, and forget.[7]

In addition to the primary separation of messages from each other by means of director and termination signals, secondary separation between parts of a single message can be achieved by reading circuits. For example, the "top-line" message identification only may be separated out and sent to bookkeeping or monitorial printers (less message texts), or addresses may be separated from texts for purposes of handling multiple-address messages (books).

34. Private-wire Telegraph Systems. Networks rented by business and government from the common carriers range in size from the simple teleprinter trunks described in Sec. 30 to industrial and government networks extending throughout the country.[8] The points served usually comprise (1) relatively few switching centers (usually one to three) interconnected by adequate facilities and (2) a large number of tributary points joined with one or another of the switching centers. Messages are

keyboard-manipulated only once, and then at point of origin; subsequent relays are through either repeaters or reperforators to teleprinters of final destination.[1]

Determination of the number and traffic-handling characteristics of the wire facilities to be employed in a projected private telegraph system and the number and location of switching centers is a solution of a problem of systems planning,[2] subject to adjustment after experience with an initial installation. The number and location of switching centers and their size can be decided upon by methods of cut and try, only after a complete 3-day sample traffic-load study and growth estimate has disclosed the daily and peak-hour loads passing between every pair of stations on the system,[3] and after these data have been related to the message capacity of the tributary lines. Small offices may be served on way-wire (multistation) circuits. Full circuit loads, justifying *direct* circuits between certain pairs and by-passing switching centers, will be revealed; these loads will be separately allocated and only the residue considered with all other fractional-channel loads. A first design attempt might assume two switching centers and their location. Availability of bunched circuit routes, their mileage, and cost would then be found from each outlying tributary station to one or the other of the switching points, taking into account the superior operation advantages of grouped circuits. A second design attempt might consist in raising the number of switching centers to three and reducing it to one. Although some national networks have around ten switching centers, the trend is to reduce them to one or two to obtain inherent advantages of minimum delay, maximum accuracy, circuit flexibility, and staffing economies which may override the costs of greater circuit mileage.

The number of trunks to be furnished to interconnect switching centers and whether they are to take a *straight-line* (backbone) or *ring* route are matters for prime decisions based upon known laws of efficiency for grouped operation[4] and upon the laws of probability applied to predicted *fall of load* and *holding time* of connection.[5]

At reperforator centers, switching may be done: (1) manually (*torn-tape transfer*), in which case the messages in received reperforated tape form are physically separated by operators and inserted in transmitters which will take them another or the final step toward destination;[6] (2) semiautomatically (push-button switching) by an operator who, upon observing the destination of each message, pushes a corresponding button to direct it across the office to the circuit which will take the message onward; or (3) fully automatically, handled, without intervention of operators, by tape-reading *selectors* (*directors*) which are responsive to selection (directing) characters (usually

two in number) preceding each message to designate its route, or its single or group destination.

Choice of type of switching operation represents a balance between cost and adequacy to render desired service. Torn-tape transfer is least expensive and is used in some large installations but is best adapted to light circuit loadings and smaller networks. Important considerations are: (1) whether the customer has particular reasons for wishing to adopt priority classification[1] of traffic movement (because it is relatively expensive to switch on a priority basis except with torn tape); (2) whether the subscriber has great need for fanning out multiple copies (books) of the same text to several or many addresses, for torn tape is less well adapted to this task than the automatic systems.

Adoption of automatic and semiautomatic systems requires full duplex operation of all lines, to prevent tape accumulations and to simplify circuitry.

Of some importance is the form of message adopted and the associated routine steps for its handling. Operational routines to be followed should ensure that all messages start printing at the left margin on a new line, clear of the preceding message; that the attack (selector or director combination) is cleared for unambiguous switching; that no fault in transmission occur which would divide a message in parts or dissociate any verifications (confirmations, collations) or supervisory instructions from the messages to which they apply; and that the message is properly terminated with the specified (knock-down, disconnect) signal combinations. The specific form of message and operating routine will, of course, be different for the torn-tape, push-button, and automatic-selector methods.

In a small simple torn-tape system, the tape output of half a dozen incoming printer-reperforators is produced in a console which also contains a corresponding number of outgoing transmitter-distributors. An operator, standing before the console, tears off one message at a time from each incoming tape at a point between messages which has been clearly marked as part of the end-of-message routine. She then examines the message for its destination and places it in the proper outgoing transmitter-distributor. If, for any reason, she cannot dispose of the tape immediately (*e.g.*, because the line is half-duplexed and is operating in the opposite direction, or because another tape is occupying the transmitter) or for some reason must hold it (*e.g.*, because other classes of message have standing priority), she clips the tape in a tape holder bearing priority labels that facilitate her subsequent handling of accumulated tape in orderly manner.

A common characteristic of a push-button or automatic reperforator switching center is that each message is reperforated twice (in tandem). The first reperforation is to receive it from one of the incoming lines; to reveal its destination for push-button or selector-switching purposes; and to make it available for high-speed cross-office transmission to the second reperforator. The purpose of the latter is to place in an orderly arrangement all messages due to leave the office over a given outbound line. Cross-office transmission is at higher speeds than either incoming or outgoing lines to make up for switching delays; it is made possible by designing the cross-office (second) reperforators to receive all five unit pulses from across the office simultaneously instead of seriatim. Speeds of 75 to 150 wpm are customary.

Special circuits used in push-button and automatic reperforator switching systems include:

Multistation circuits (*way wires*)[2] with provision either for lockout of idle stations until a busy station has finished sending or for making automatic periodic contact with each station in turn and establishing, in rotation, outlets to the switching office for those stations offering traffic (pickup). In the reverse (delivery) direction, automatic starting of printers, in rotation, for only those stations to be recipients of traffic on hand.

Station-control circuits at a multistation line point, which, upon reception of a unique or group office designator, connect teleprinter equipment to the line, then cut themselves out of circuit so as not to be responsive to the same letter sequences in traffic.

[1] Hyde, G. A. M., A Long Distance Automatic Teleprinter Exchange with Manual Priority Services, *Trans. AIEE*, **58**, 375, 1939.

[2] Adams, M. D., The Development of Western Union Switching Systems, *WUTR*, **4**, 69, 1950.

Reading (*director*) *control* circuits, set to recognize combinations of given characters appearing in a given order and to take appropriate switching action implied by the combination. Action may be delayed by a *sequencing* circuit, which makes commencement of a second activity dependent upon completion of a first.

Director circuits, which determine the office outlet by reading incoming director signals, which test the availability of a reperforator-transmitter at the outlet, then route the message cross-office.

Link circuits (connector switches), multipoint rotary or crossbar switch circuits, which complete cross-office connections between incoming and outgoing lines.

Load-distributor circuits, composed of (1) transmitter finder rotary switches which seek out idle sending trunks among an interswitching-center trunk group, and (2) load-distributor rotary switches which function to connect in even fashion any one of the cross-office circuits, serving that trunk group, to a trunk found by the transmitter finder, thus by-passing busy channels.

Multiple-address circuits, which respond to special two-letter group director codes, then: (1) read seriatim the codes of destinations; (2) for each code in sequence, complete a cross-office connection, hold it, block the outlet against other use; (3) in the case of each such connection to another switching office insert a group director code indicating that multiple address handling is required; (4) send the message to all outlets simultaneously (*master-send* circuit).

Group-code circuits which find uniquely grouped multiple-address routes by means of a single director combination, dispensing with the lists of destinations.

Intercept (*spill-over*) circuits to reperforators, provided to receive messages (1) requiring special supervision such as priority, deferment, special attention, closed-office storage (*willful intercept*), or (2) involved in false calls and other switching troubles (fail-safe *automatic intercept*).

Flip-flop (*walking-beam*) sequencing circuits, which relate two instruments (such as transmitters) to a single sequential activity (such as sending to line) alternately. The knock-down (termination) of the unit of work being performed by the first activates the second, and vice versa. The transmitter loaded first is first to start.

Safeguards[1] for handling traffic without loss due to circuit interruptions, switching errors, or handling mixups have warranted the development of special expedients, among which are:

Avoidance of the letters T, O, M, V, in the first director signal, as being particularly susceptible of occurring during preceding stop interval, resulting in wrong switching; avoidance of H, the end-of-message indicator, and Z, the cut-in signal for a receiving-only teleprinter.

Alarms on intercept circuits; alarms to indicate line failure, switching-circuit failure, or delay, printer, and reperforator failure, failure of tape to feed, torn tape, low tape supply. In certain instances the alarm also causes the failed equipment to test *busy*, against further use.

Read-back circuit alarm, used following inconsistent comparison of received numbers with numbering machines.

No-switch alarm which sounds when a switching unit reads a director combination that has not been assigned for use.

Automatic supplying of end-of-message (knock-down) signal after 45 sec nonreceipt.

Diary teleprinters, which print, on a single record, top-line identifying data for every message switched through a reperforator center.

Among the specialized equipment or usages developed for switching systems are:

Reperforators, Sec. 44.

Printer-perforators, which translate into printed characters the holes punched in the tape, in either of two aspects: (1) on the marginal edge of tape, in register with the punched holes; (2) on chadless (hinged, partial perforations) tape, in the middle of the tape, six center holes behind the punched signals.

Perforator-transmitters (FRXD), a swivel combination the tape storage within which is reduced to zero after reperforation ceases, avoiding tape feed-out to clear the message.

Transmitter-distributors, combining in one instrument start-stop distributor and tape-transmission functions.

Tape editors, for notching the edge of tape at a point where it is desired to stop its transmission for the purpose of using a keyboard to make a correction or insertion in the text.[2]

[2] Wishart, R. S., and G. G. Light, Switching to Patrons' Teleprinter Tie-lines, *WUTR*, **3**, 51, 1949.

Automatic numbering machines, which enter a transmitting circuit at the beginning of each message and insert a consecutive three-figure line number and circuit-identifying characters.

Use of rotary switches to connect an incoming line to a first-idle outgoing reperforator, trunk, or outlet for local delivery copies.

***Line finders*—rotary switches used to concentrate the use of a few connector switches among many lightly loaded receiving circuits for the purpose of avoiding incoming reperforation.**

35. Teletypewriter Exchange Systems (see Chap. 24, Sec. 69). Teletypewriters are switched through central offices for temporary interconnection between calling and called subscribers on a time-charge basis in a manner similar to long-distance telephony. The service (TWX) is offered in the United States by the telephone companies[1] on a separate national manually switched network using telegraph circuits derived from telephone physical and carrier facilities. In Europe the several national systems of posts, telegraphs, and telephones offer similar interconnections (Telex), national and international, on a network generally using derived circuits, generally separate from telephone on the subscriber's premises, and generally manually switched. Some European countries have machine-switched Telex; in some the subscriber's tie lines have done and still do alternate duty for telephone and modulated-carrier telegraphy. The United States overseas radiotelegraph carriers offer interconnections between TWX in the United States and Telex abroad.

TWX installations in the United States feature supervisory circuits in switchboards[2] at the principal switching points, automatic subswitching centers controlled by switching points,[3] universality of keyboards, a directory of subscribers, uniformity of transmission, and a high degree of accuracy (see Sec. 20). Connections are half-duplex (to and fro) and a subscriber-to-subscriber connection is made before service begins to be timed. *Conference connections* may be set up involving more than two subscribers.

Telex in Europe[4] places emphasis upon use of a connection-confirming *"Who Are You?" key* built into the teleprinters, upon use of Baudot code, and upon operating routines. The teleprinters contain an auxiliary cam with axis transverse to the printer-selecting bars. Upon making a single rotation initiated from the distant end of the circuit, this cam will transmit to line the called subscriber's Telex identifying number. The calling subscriber, having been informed his connection has been completed, tests it out by signaling upper-case D, which has been reserved for the identity release signal. This signal will thereupon trip the cam release on the called printer, furnishing the calling subscriber with printed confirmation of correct connection and testing all parts of the two-way communication circuit and functions except the paper, ribbon, and type bars, and without waiting for the called party to come in.

36. Time-division Multiplex (TDM). Multiplex printer circuits, on which the utilized frequency spectrum is apportioned among channels by synchronously commutating brushes instead of by filter bands, have the feature of packing spectrum space more tightly than can carrier or facsimile, hence are used on limited-frequency circuits, like ocean cables, overseas radiotelegraphs,[5] and specialized land-line circuits, such as the *varioplex*, requiring a wider-than-teleprinter (23-cps) band (see also Chap. 24, Sec. 23).

Hoover, R., The Application of Western Union Multiplex to Navy Radio, *WUTR*, **2**, 29, 1948. Peterman, W. C., and A. Mine, Four/two Channel Time-division-multiplex Telegraph System for Long-distance Radio Circuits, *Elec. Commun.*, **28**, 127, 1951.

A unidirectional three-channel five-unit multiplex faceplate has 15 segments in a ring, swept by a continuously rotating brush connected to line. For handling the five-unit Baudot code in unit sequence on each channel, the faceplate is divided into three equal sectors of five segments each, each sector serving one operator and taking away from his transmitter one letter of his message every time the brush makes one revolution. At the opposite end of the circuit there is a synchronous brush, a corresponding faceplate, 15 segments, a 120-deg sector, a printer, and a receiving operator for each channel.

It would be possible to arrange each faceplate with 21 segments, to each seven of which a start-stop teleprinter might be connected. But assuming that measures are at hand for maintaining synchronism of the brushes (their rotation never stops),[1] the start and stop pulses are superfluous and can be omitted, whence the first spectrum saving of multiplex over start-stop: the code is shorter, in ratio 5:7.

A second saving appears when TDMs use carriers for their line—that is, when channels on a pair of wires, made available by frequency division, are themselves time-divided (Chap. 24, Sec. 24). The three-channel 60-wpm 45-cps multiplex will fit as nicely into a 150-cps frequency slot as will one 60-wpm 23-cps start-stop teleprinter (at least for one carrier section, be it 100 miles in length or transcontinental). The reason is linked with distortion:[2] Multiplex's five units are each subject to total distortion (that is, late or early crossing of the reference axis in relation to perfect signals). So are teleprinter's seven units, including the stop pulse (which matters little if at all), but also including the start pulse, which is most important because if it is late or early its distortion is additive to the separate distortions of the five intelligence units, throwing them further off and destroying margin. Multiplex has no such trigger mechanism and is not subject to double jeopardy as described; and experience has shown[2] that output per telegraph carrier channel can be doubled and trebled with multiplex. Start-stop teleprinter has some overriding advantages which make it a favorite, but it requires more spectrum space than the multiplex, which in-phases on the train of received signals, with no lost time.

Where TDM methods are in use, the practical number of channels is either 1, 2, 3, 4, 5, 6, 8, or 12. Mechanical distributors have prevailed, but electronic versions have been proposed[3] and are in use.[4] Multiplexes may be paired for complementary opposite-directional full-duplex use.

When so duplexed they may be equipped for varioplex operation;[5] to a three-channel faceplate a machine switching unit may be used to admit a fourth pair (or more) of users, the channel pattern going to line being then changed from normal ABC-ABC-ABC-ABC to ABC-DAB-CDA-BCD. The 60-wpm speed originally available to each of three is thereby cut to three-fourths, or 45 wpm per channel upon entry of the fourth user, and would be further cut to 36 wpm upon entry of a fifth. Laws of chance and judicious assignment of as many as 60 pairs of users on subchannels prevent peaks of simultaneous use from occurring with any consequent impractically low transmission speeds.

The TDM principle is the basis of broad-band pulse-modulation[6] systems used in microwave applications for simultaneous telephony-telegraphy and in mobile tele-

metering service. In that usage, extra signals are used for maintaining synchronism instead of phasing the receiver on the signal train. In wire applications, TDM is expected to develop usefulness in integrated data processing.

37. Nonlanguage Data Transmission. Fringes of common interest between business machines and communication lines are created whenever associated parts of office machines are required to operate in separated locations.[1] The teleprinter is an example: a typewriter keyboard separated from its typing platen. A multiplicity of typesetting machines may be controlled from a single distant keyboard.[2] Billing and listing machines can be dissected and their components separated for remote accounting.[3] Telegraphic methods may be applied to inventory control,[4] to ticket reservations,[5] to reordering of mercantile stocks; to the posting, display, filing, and producing of information on call (*access*, in the computer technique), and for the consolidation of statistical reports, compiling of payrolls, and issuance of vouchers, where distance between organizational units is a factor.

Teleprinter tapes and techniques are also used in the input, output, and memory systems of high-speed computers;[6] in the feeding of control information to lathes, milling machines,[7] textile machinery, and other forms of automation. In the factory there is a similarity between controlling individual machines, batteries of machines, and entire factory units in ganged operation, on the one hand, and group-director and master-send multiple-telegram methods, on the other.[8] Similarly, in the business office there is an alliance and demonstrated convertibility[9] between the punched holes of business-machine cards, as a result of which the storage, memory, entry, and access systems[10] of both may be combined in novel and useful forms of office automation;[11] *e.g.*, the sorting and tabulating features of cards may be combined with the flexibility of tape in interpolating stored or manually inserted information among items of new intelligence by telegraph selector-director methods (editing). Codes included in the tape will stop and restart the transmitter for keyboard insertions; deletions are made by stepping tape through transmitters having deactivated pins.

While most technical data-processing activity is being directed to the design of all these machines on a local basis (*i.e.*, intraoffice, intraplant), much thought is also being given to their integration: determining the role of intercity lines to feed to their inputs information and control signals and to distribute their outputs to points of utilization (integrated data processing—IDP).[12] The existing five-unit telegraph systems (public message, teletypewriter exchange, and private wire) are logical building blocks of integrated systems; six-unit, seven-unit, and eight-unit codes are obvious practicable extensions of five-unit characters in relation to the prevailing 150-cps and 170-cps carrier-channel separations; electronic time-division and counting techniques may be given an outlet of higher magnitude on half or whole v-f bands. Devices are readily contrived to send six-, seven-, or eight-unit characters over existing five-unit channels,

thus providing for the transmission of a useful admixture of administrative dispatches and nonlanguage data at will over present lines without substantial changes.

Paper tape and, recently, magnetic tape, prepared from source documents, like order forms, waybills, time cards, sales reports, or statistics, may be coded for access, transmitted over wires, and reused with stored information in the preparation of such other documents as management reports, production scheduling, inventories, periodic cash balances and payrolls, or to activate other data-processing equipment. Separation of data by classes is accomplished by selector codes. Tape so used is called *common-language tape*. In its storage and reuse, without manual intervention, but with deletions (by idling through) of obsolete and the addition of variable material, it is referred to as *self-perpetuating tape*. Multiple forms, tabulations, control of carbon and multilith copies, and operating procedures must be exactly prescribed to employ self-perpetuating common-language tape.[1]

38. Error-checking Systems (see Chap. 24, Sec. 8). Information handled without context makes extra demands upon the operating margins of communication systems, creating an ascending scale of *bit-accuracy* standards, from telephony at one extreme, through telegraphic plain language, machine encryption, pronounceable code, cipher, and figures, to data transmission at the other. Examination of the order of this listing will show descending order of redundancy in textual content, hence increasing difficulty on the part of the recipient to "read through" errors without securing corrections.

The *fixed-ratio* error-checking code used in radiotelegraphy is not employed on wires for reasons stated in Sec. 20. However, since accuracies of the order of 100 million characters per error are attributed[2] to the electromechanical systems of modern computers, a demand for their intercity integration by wire has given impetus to matching computer accuracy in telegraphy, inclusive of the terminal information-interchange apparatus as well as the lines. At a transmission rate of 100 wpm and an accuracy rate of 1 error per 100 million characters, it requires, on the average, 2 months of 10-hr days to develop one error.

Because of the complexity of their equipment, designers of computers have found it necessary, even when all operations are local, to incorporate *error-detecting* (and in some cases *error-correcting*) methods into their machines.[3] Reduced to terms of five-unit perforator-tape telegraphic transmission,[4] these involve the regularly spaced automatic insertion of extra "blind" characters into the tape which convey tally information regarding some statistical feature of the transmitted tape, against which the receiving reperforator can *check*—passing on those groups which do check but locking itself up on groups where transmission discrepancies are revealed. The group of intelligence characters between the check characters is designated a *word;* such words are of any convenient length—say, twenty five-unit characters, representing 100 binaries or an equivalent number of decimal digits. The number of characters in a *check group* might be four[5]—a burden of 20 per cent, equal to the adding of a sixth unit to the five-unit code. The nature of the check made by these four check characters is called a *parity check* of mark units transmitted in the 20 vertical columns and 5 horizontal lines of holes in the 100-bit *grid* under examination. "Mentally," the machine rearranges the grid into a 10 by 10 square; counts the marks first in each column, then in each line, assigning to each *even* count the parity value of M and to each *odd* count the parity value of S; finally punches these 20 M and S parity values seriatim in the 20 holes of the four-character test group.

[5] Gryb, *op. cit.*

At the final receiving reperforator the same tests are applied while the intelligence tape is being prepared there, but the 20 M and S parity values are stored, rather than punched, for comparison with the parity tally received over the line. If a transmission error occurs in the word under test, an *even* count (instead of *odd*, or vice versa) will show up as a discrepancy in an indicated column and on an indicated line, intersecting at the errored bit. Correction is obtained by retransmission of the errored character or errored word. The check characters having been automatically eliminated from the reperforated tape, the latter is ready to be fed, error-free, into the input of the computer. Such systems[1] are in the experimental stage.

Pertinent to the subject of error-checking systems are the subject and evaluation of *absolute line delay*, which become significant if *automatic error correction* (ARQ—Chap. 24, Sec. 71) is employed,[2] since it involves round-trip cumulative time to send by wire from A to B, receive and check any inaccuracy at B, seize the transmitter at B, switch the receiver at A, back-space at A, and repeat the character accurately from A to B. To lesser degree, absolute delay concerns *answer back* (Sec. 35) and other round-trip uses of equipment.

The figures of one-way absolute delay in milliseconds may be typically approximated for a 1,000-mile single section of carrier as shown in Table 5. These figures should not be confused with signal distortion expressed in milliseconds variation from ideal (Sec. 19).

Table 5. One-way Absolute Delay

Component of Delay	Delay, Millisec
Sending and receiving mechanisms	30
Carrier-vehicle band equipment (1 millisec per carrier section)	1
Line-propagation time, including repeaters (8 μsec per mile)	8
Total absolute delay:	
For a 1,000-mile 1-section carrier	39
For a 3,000-mile 2-section carrier	56
For a 3,000-mile 3-section radio beam	39

39. Telegraphic Encryption. Privacy in telegraphic communication is in part safeguarded by the public's use of code and cipher and by the complexity of wire circuits and equipment employed. Special measures have to be adopted if it is desired to obtain a military level of security from wire-circuit surveillance or interception. These special measures are themselves military secrets. Some of those used in the past have been based upon published methods.[3]

A scheme used in the First World War and later may be illustrated as though, at the sending end, two ordinary perforated five-unit tapes were to be fed simultaneously into two distributor transmitters—one the intelligence tape, the other a key tape. As the successive characters were sensed by the two transmitters, a character from each tape at a time, and each of the corresponding five units of each character in sequence, transmission of unit polarities to line would be determined by identities in the two tapes (producing marks) or disparities between the two (producing spaces). Thus the intelligence units sent to line would not be those of either tape but would constitute a running report on the correspondence (or lack of it) of the two, hence unintelligible if intercepted without a key tape.

At the receiving end there would also be two local transmitters, one using an exact duplicate of the key tape, the other using a tape reperforated from the line's running report of unit correspondence. The correspondence signals would be used to modify the key-tape signals so that the original intelligence would emerge in the receiving cir-

cuit and directly operate the teleprinter. The security of the system would depend upon the encryption adequacy, feasibility of duplication, safeguarding, and nonreuse of the key tapes.

40. Facsimile Telegraph Systems. Many thousands of photoelectric scanning, black-and-white dry-recording facsimile machines (see Chap. 23) are in use for local pickup and delivery of telegrams[1] over inexpensive v-f local wire pairs in cable. The useful city range without repeaters is about 5 miles in cable. A great deal of engineering has been done on the concentration of central-office and subcenter equipment[2] to permit a number of machines and pairs so terminated to serve several times their number of outlying machines. Many auxiliary devices and circuits have also been produced[3] to handle and discharge sending and receiving blanks to speed up the handling of such facsimile copy as telegrams and train tickets.[4]

There is no barrier in the technology against provision of telefacsimile exchange service with full automatic selector switching. For through circuits the transmission requirements are little more severe than for telephony;[5] for transmission involving storage en route, magnetic recording has been experimentally successful, though signal regeneration at repeaters has yet to be accomplished. In applying facsimile to intercity services, its v-f carrier-band-width requirement (1,336 bits per net scanned typescript character) handicaps it[6] in competition with teleprinters (7½ bits per character plus a frequency-division carrier guard-band loading factor of $^{150}\!/_{23}$, or about 50 bits per net printed character). Even vestigial-side-band transmission[7] narrows the discrepancy only in degree. Further cheapening of intercity lines, in conjunction with different yardsticks of tariffing such as per-page rates, might change the present outlook. With the exception of weather and military mapping, of tickets, and of pictures for the press, market surveys and experimental runs have not confirmed the existence of more imaginative uses of facsimile for transmission of graphic information than for typescript readily handled by teleprinters.

TELEGRAPH APPARATUS

41. Organizations of Apparatus. Most private-wire telegraph equipment is obtained from the catalogue offerings of the telegraph and telephone companies or specialty manufacturers, or assembled by making circuit adaptations involving such standard equipment. A principal item is the *teleprinter*, the model most widely employed being universally known as type 15, or, with perforator and distributor-transmitter accouterments (for *off-line* operation), as type 19. The most recent, and a higher-speed, printer is the type 28, a somewhat comprehensive description of which[8] is warranted here (Sec. 43). Another, but smaller, item is the *main-line relay*, whose universality entitles it to treatment from the viewpoint of design (Sec. 42).

Customers' equipment[9] is generally console-mounted, incoming and outgoing consoles being separately standardized. Printers are operated from a seated position; switching is done in a standing position. Consoles are unitized and made interchangeable, lending themselves to system expansion or contraction without change. Major equipment, packaged items, appliqués, subassemblies, and nodules are removable[10]

and, when in trouble, are handled on the basis of "swap-now-fix-later." Removal is facilitated by general use of multipoint base-jack or clip connections or multiconductor Jones plugs and jacks.[1]

Equipment units and wiring are made as accessible as possible by use of pivoted chassis or drawer construction. Flexibility is carried over into such items as a-c bus feeders and other power-supply wiring.[2] Extreme miniaturization and printed circuitry have not been widely employed in telegraphy. Much has been done, however, to attain compactness in units for mounting in standard 19-in. relay racks. One expedient adopted, for example, in design of filters for carriers, is to use more C and less space-consuming L in LC circuits.[3]

Provision is made for ventilation of apparatus and exhausting of room air to dissipate the heat losses encountered in apparatus. Cabinet blowers and room-air-conditioning units are fitted with air filters which give additional protection against accumulations of dust and lint on switching contacts. Removal of moisture concurrently with air cooling aids in the mechanical processing of perforated tape.[4]

Bay-mounted auxiliary equipment is set off to one side of a floor layout. Connections are provided to both wire and radio circuits by standardized transducers.

Repair benches and testing equipment are located adjacent to equipment installations. Some test circuits are wired in through cabling; in other cases it is advantageous to have test equipment mounted on dollies, to be rolled to position and there plugged in to test jacks. Portable, "rigidized" test equipment is furnished for common use of switching centers and offices tributary to them.

Military installations make special demands for shock mounting of rugged apparatus, imperviousness to moisture and mold (tropicalization) and to extremes of heat and cold, ease of transport (light weight, portability, and cabinet mountings), and tolerance of extreme power-supply voltage variations.[5]

42. Main-line Relays. Many thousands of relays are used in telegraph service, most of which are of leaf- or wire-spring type, generally known as Craft relays, even more prevalent in telephone-switching service. However, the telegraph main-line polar relay,[6] which follows plus-minus emf signal-arrival curves, is appropriately illustrative of principles of design.[7]

Polar Relays. These are more sensitive than single-current relays. In general two magnetic paths must be provided for the magnetic fluxes: one for the flux produced by the permanent magnet, the other for the flux produced by the operating current. These paths usually are arranged in the form of a bridge or similar balanced configuration so that a center position of the armature exists with respect to the permanent-magnet flux. The path for the flux produced by the operating current is disposed in the bridge in such a manner that the magnetic forces on the armature are unbalanced when operating flux exists so that the armature movement depends upon the direction of the operating current.

Figure 21 shows the magnetic conformations of a number of widely used polar relays. In the figure, each permanent magnet and its flux path are shown in heavy outline and the operating-current flux paths in lighter outline. The diagrams do not indicate relative dimensions or mechanical arrangement of the parts.

Actuating coils may be four in number: two main coils, which must operate within specified limits of current, and two auxiliary coils having half the number of turns of the main coils. The four coils may be poled and connected in various combinations. In one application, one auxiliary coil is caused to set up a force, as soon as the contact tongue is banked, say, on mark, to tend to help it leave for space upon decay of main-

line current and somewhat in anticipation of full arrival of the next wave front; the other auxiliary coil is wired into a circuit which will energize it (hence, the armature) with a capacitor kick the instant the mark contact is actually broken. (The same coils work in reverse when the tongue is on space, giving double impetus to hasten its movement in response to a new mark arrival curve.)

In another application the auxiliary coils are wired into a vibrating circuit whose frequency matches that of bit reversals coming in over the line, whose energy is generated locally either by a tuned circuit or by auxiliary rings on the receiving distributor, and whose magnitude is equal to the received signal. Thus, the combined signals act to aid or to oppose, hence to regenerate the incoming signal (*cf.* Sec. 28, Fig. 14).

Relay Construction. In any relay, the flux reacts upon an armature which bears a tongue with contact points. The motion of the tongue between mark and space is not less than 0.006 in., but because of the foregoing auxiliary expedients its transit time (of the order of 1.2 millisec) is less than that governed by line current (10 to 35 ma, roughly 3 watts or +35 dbm), flux, and steepness of arrival curve alone.

Armatures should work freely throughout the life of bearings. Current-carrying bearings are minutely because of high current density through microscopic areas even when shunted by jumper wires, and are thus subject to seizing. Hole-and-sleeve pivots are therefore suspect; knife-edge or rolling-edge bearings are preferred; some modern relay armatures are spring-mounted and work without bearings.

Armatures may be mounted to provide two or three positions of the contacts. In the common two-position relay, the tongue rests upon either one contact or the other depending upon the direction of the operating current. In the three-position relay, the tongue stands midway between the two contacts when no operating current exists. This condition is usually provided by a spring mounting of appropriate stiffness to counteract the tendency of the permanent-magnet flux to hold the tongue on either one contact or the other.

FIG. 21. Magnetic circuits of commonly used relays: (A) Siemens (European); (B) Wheatstone; (C) type 17 Western Union; (D) Carpenter (British); (E) U.S. modification of (D); (F) type 215 Western Electric; (G) inefficient type—path of operating flux includes the permanent magnet (of high reluctance); (H) type 202 Western Union.

Usually some means is incorporated in relay structures to eliminate or minimize contact bounce; for example, compliance spring arrangements associated with the contacts are used to dissipate energy in sliding friction to arrest the motion of the armature. In type 202-A, a single spring is used for mounting and to implement the bounce-absorbing principle by dissipating the energy in sliding friction at the contacts. Usually a small bounce is unimportant since the commonly used *spark killers* (Sec. 17, Fig. 8*A*) across the contacts largely filter out such short-period variations.

To facilitate quick removal for replacement, adjustment, repair, or overhaul, main-line relays are universally base-jack- or plug-mounted.

Contacts. There is probably no universal contact material best suited to all specific applications and ensuring satisfactory operation and long contact life. The particu-

lar material selected depends upon many factors such as filming, pitting, and material transfer. Materials such as silver, palladium, and their commonly used alloys have excellent conductivity. Tungsten is resistant to mechanical wear but has considerably less contact conductivity. Tungsten carbide is free of many of the defects of other contact materials but has much higher contact resistance. Consequently tungsten carbide contacts must be operated at relatively high contact pressure. But because a relay equipped with tungsten carbide contacts will perform several billion operations before readjustment becomes necessary, they are favored for low maintenance cost and trouble-free operation in the 202-A relay and other types.

The importance of relays as circuit elements justifies references to the literature for further information.[1]

43. Model 28 Teletypewriter (see also Chap. 24, Sec. 69). Since the widely used 60-speed (368 operations per min) start-stop teletypewriter type 15 is described in Sec. 30,[2] the more recent, higher-speed type 28 merits description here.[3] Type 15 printers operate, with special attention, at 75-speed; type 28 is designed for 100- and will operate at 125-speed. Speeds of 60 to 66 wpm are well suited to the capacity of keyboard operators. Higher circuit (channel) speeds are made practicable if transmission is to be from prechecked, reperforated, stored, or otherwise accumulated tape. With accurate wire transmission, receiving puts no practical ceiling on speed, for printer copy requires only cursory examination by receiving operators, if not produced by unattended printers. The trend, therefore, is to higher circuit operating speeds.

There are nine code bars in the model 28 teleprinter (Fig. 22). The first, second, third, fourth, and fifth pulse code bars are positioned to marking or spacing, that is, to the left or to the right as viewed from the front of the teleprinter, by the selector mechanism. The positioning of the *common* code bar is determined by the position of the first and second pulse code bars, and has no other function than the vertical positioning of the type box.

The *suppression*, *zero*, and *letters-figures shift* code bars are positioned to marking or spacing by functions in the *stunt box*.

The code bars have two separate and distinct functions. First, after having been positioned for a particular character by the selector mechanism, they cause the type-box positioning mechanism, by means of mechanical linkages, to position the *type box* with respect to the *printing hammer*, so that the character whose code is set up on the first, second, third, fourth, and fifth pulse code bars will be printed. Second, they cause typing-control functions to be performed within the printer mechanically, or at a remote location by means of switching.

Fig. 22. Code bar arrangement showing the five intelligence selector bars and auxiliary bars.

In the typing unit,[1] the type pallets are mounted in a rectangular type box approximately ½ in. thick, 1 in. wide, and 2 in. long. The weight of this type box and its associated *carriage* is only 8 oz, about one-tenth as much as the type-carriage assembly model 15. This permits the carriage to return from the right to the left margin within the time of two characters, even at 100 wpm.

The *type pallets* in the left half of the type box (Fig. 23) are letters and those in the right half are figures. When the type box is in position to print letters, a *printing-position pointer* in the center of the top of the letters half of the box is just below the position in which the next character will be printed. When a *figures-shift* signal is received by the typing unit, the type box shifts to the left so that the figures half of the type box is in the printing position.

Each half of the type box consists of vertical rows of type pallets, four on each side of the printing-position pointer, and four horizontal rows deep. The character to be printed is selected by moving the type box vertically and horizontally to move the type pallet into

Fig. 23. Type-box code chart showing location of type pallets.

the printing position. The four possible combinations of the first and second pulses are used to determine which of the four horizontal rows of type will be selected. The third pulse determines whether the type box will shift to the right or to the left from its rest position, and the fourth and fifth pulses determine how far it will shift from its rest position. Each of the four horizontal rows has a different combination of the first and second pulses. Each character to the left of the printing-position pointer has a marking third pulse and each character to the right of the pointer has a spacing third pulse. Also, the combinations

[1] Smith. *op. cit.*

of the fourth and fifth pulses are different for each of the four possible vertical rows on either side of the center position.

After the type box has been positioned, a spring-operated *print hammer* which moves with the type box is unlatched and allowed to drive the selected type pallet against the ribbon and paper to print the character. The print hammer is then reset to its latched position and the type box is returned to its rest position. When the signal for a nonprinting function is received, the type box is positioned in the usual manner and the print hammer is operated; however, *dummy* type pallets which do not print are placed in each of the nonprinting positions, so that no impression is made on the paper. A *spacing-suppression* mechanism prevents the type box and carriage from spacing when a nonprinting function is selected.

Another advantage gained by use of the type box, in addition to its light weight, is the ease with which the entire type box can be removed and replaced. For example, a standard *communication* type box can be removed and a *weather-symbol* type box installed in its place in a matter of seconds. Each character is mounted on a separate type pallet, so that it is not possible to print part of a letter and part of its associated upper-case character at the same time as in the case of type bars. Since the type box shifts to change from letters to figures, the platen remains stationary except during a *line feed*, thus reducing paper *creep* when multicopy paper is used and also eliminating the shock produced by shifting a heavy platen or type-bar assembly from the letters to the figures position. Type alignment is controlled in manufacture and it is never necessary to solder type pallets in position with a soldering fixture to obtain accurate alignment, as it is on a typebar teleprinter. When it is necessary to replace a defective part, the entire type box can be replaced by a spare without removing the teleprinter from service.

Selecting Mechanism. The principle of operation of the selecting mechanism is the same as in the model 15 with differences in detail of the cam-and-lever assembly. A *mark-space lock-lever* cam and five *selector* cams are released and start rotating when the start pulse, preceding the five units of intelligence, is received. An interlocking arrangement ensures that a selecting armature is unlatched only momentarily at the time of each signal transition so that it is free to respond to the incoming signals, whereupon the armature is locked in its selected position until just before the next signal transition is due to occur. Thus a virtually *terminally regenerated* signal is passed through the cam-lever transfer mechanism for the proper mark-or-space positioning of five selectively slotted *code bars*. In addition to the five intelligence transfer levers, there is a sixth or common transfer lever, which is contrived so that, if either the No. 1 or the No. 2 transfer lever moves to the marking position, the common transfer lever will also move to the marking position.

Fig. 24. Code-bar shift mechanism.

Shortly after the five selector levers have operated in sequence and set up the received code combination on the code-bar shift bars, a shift-lever link is driven upward by a code-bar positioning clutch and associated mechanism. As the shift-lever link rises (Fig. 24), the two code-bar shift levers engage notches on the code-bar shift bars and position them to the right or left depending on whether the shift bars are in the spacing or marking position.

To control the vertical positioning of the type box to print the selected character, the Nos. 1 and 2 code bars and the common code bar have projections on their right ends which extend beyond the code-bar guide (Fig. 22). In addition, there is a suppression code bar, marked "Sup" in Fig. 22, which extends beyond the code-bar guide. When the No. 1, 2, or the common code bar is in the spacing position, the projection on the bar will be in the path of point *a* on vertical positioning levers (Fig. 25). When one of these code bars is in the marking position, it will be moved to the left far enough so that the projection on the code bar will not be in the path of the vertical positioning levers. The projection on the suppression code bar, however, is always in the path of the vertical positioning levers.

Shortly after the code bars have been positioned, a type-box clutch and associated mechanism thrust a driving lever (Fig. 25) upward. This lever has attached to it an assembly consisting of the three vertical positioning levers. The type-box carriage track is fastened to the upper of these three levers, as shown in Fig. 25, so that the carriage track and type box move upward as the vertical positioning levers are driven upward. (There are actually two driving levers and two sets of vertical positioning levers, one on each side of the typing box, but only the right-hand set is shown.) As these levers move upward, point *a* on the middle lever strikes the projection on the lowest code bar which is in the spacing position. This causes the lever to rotate about its pivot *b*, and the lower end of the middle lever rotates counterclockwise so that the knee joint buckles at the pivot *c*. As the driving lever continues to rise, the two lower levers continue to buckle and the upper lever stops its upward travel. A latch (not shown) momentarily locks the upper lever in its uppermost position until after the selected character has been printed. Thus the combination of the first and second pulses received by the teleprinter determines which of the four horizontal rows of type will be brought into position to print.
FIG. 25. Vertical positioning mechanism.

The position of the No. 3 code bar determines in which direction the type box will be shifted by determining which of two horizontal positioning drive links will be allowed to position the type box. When the No. 3 code bar is in the marking position, for example, a knee link which drives the type box to the left is buckled and another knee link which drives the type box to the right is allowed to operate and move the type box to the right. When the No. 3 code bar is in the spacing position, the knee link which drives the type box to the right is buckled and the other knee link is allowed to drive the type box to the left.

The combination of the fourth and fifth pulses received by the teleprinter determines how far the type box will shift horizontally from its rest position. The mechanism which accomplishes this operates on the same principle as the vertical positioning mechanism; that is, the Nos. 4 and 5 code bars both operate bell cranks which in turn operate horizontal stop slides. A common horizontal stop slide equipped with two stopping surfaces is operated by either of the other two slides so that four stop positions are obtained to correspond to the four possible combinations of the fourth and fifth pulses. These four stop positions determine at what point a horizontal positioning knee linkage will be buckled.

Two code bars not previously identified are shown in Fig. 22. The code bar marked *O* is part of the automatic carriage return and line-feed linkage and the one marked *S* is the letters-figures shift bar, the position of which determines which half of the type box will be in the printing position. These are controlled through a major assembly, the function box, which not only controls the typewriter "stunts" but has many collateral switching functions.

Function Box. This is located behind the code bars and extends across the entire width of the typing unit. Each of the code bars is notched at the rear in an identical pattern. These notches in the code bars are used in conjunction with function bars in the *stunt box* to select a function. When a particular combination for which a function bar is coded is set up on the code bars, the uniquely complete row of slots which represents it will first be sensed, then communicated by a bail-driven linkage to a function lever. The motion of this lever is used to initiate the desired function. The movement of the *lower end* of the lever is used to perform mechanical printer functions through appropriate mechanisms associated with the various function *levers*. A projection on the lower end of nonprinting function levers causes type spacing to be suppressed when a nonprinting function is selected. The upper end of the function levers is used to operate contacts for switching or to actuate other functions.

Stunt Box. There are 42 slots in the stunt box, each of which will accommodate a function bar and its associated mechanism. Some of these positions are required for such com-

mon functions as line feed, carriage return, word space, figures shift, letters shift, and bell signal; to these may be added horizontal tabulating, back spacing, automatic paper feed-out, sprocket feed, indexing to standard office forms, and similar mechanical elaborations of the typewriter as an office machine adapted to integrated data processing.

The remaining positions are available for other purposes. Since the function bars are coded (rather than the code bars), a function bar coded for any desired character, either upper or lower case, can be placed in any vacant slot in the function box. A function bar may also be coded to respond to both upper and lower case.

Some of the already explored[1] examples of versatility of the stunt box as a telegraph-operating adjunct are: (1) The function lever's switching contacts can be "make" contacts or "break" contacts. The combination of two sets of contacts, one make and one break, can be activated simultaneously to provide "transfer" contacts by means of activating two function-bar mechanisms on the same character. (2) A function may be performed only upon the reception of a stated sequence of two or more characters—that is, the function box may be used as a reading device to watch for and respond to given sequences of characters, like two-letter switching signals following a disconnect signal. (3) An electrical switch mechanism activated by a mechanical function in the stunt box can be used for remote control of some associated apparatus, like cutting in a reperforator upon receiving a particular character or a sequence of characters. In case of a sequence of characters, the last function-bar mechanism of the sequence will activate the switch mechanism. By adopting certain measures the reperforator may be left cut in so it can follow line signals. (4) By means of sequence-signal control of the suppression code bar the printer may alternately be thrown into "print case" or "stunt case." Among other things this makes it possible to select by single (if desired) call letters a number of teleprinters connected in series on a way wire. Stations *A*, *B*, *C* may be selected by those letters while printers are in stunt case; they will not falsely be selected by the occurrence of those letters in telegrams being transmitted while the printers are in print case. (5) For data-processing applications the stunt box can be equipped to control transmitters, reperforators, or other teleprinters. Data to be transmitted usually contain a great deal of constant material. This material can be stored in a master tape. When the master tape is placed in a transmitter, the stunt box can be used to stop and start the transmitter for manual insertion of variable data or insertion of data by another transmitter. The stunt box will also *edit* the information being transmitted by means of cutting in and out several reperforators with switching characters to select only the desired information that is to be retransmitted to various destinations. (6) By taking advantage of the machine's responsiveness to the suppression of printing or spacing, its versatility as a control mechanism is almost without limit.

44. Reperforators and Transmitters. The mechanisms common to a five-unit, Baudot code, telegraph-keyboard tape perforator and a five-unit teleprinter are similar mechanically interconnected grids, in configuration not unlike a crossbar switch, consisting of 32 actuating (in the perforator keyboard) or actuated (in the printer typing-mechanism) levers and, at right angles to them, five code bars which take up mark or space positions as a result (in the perforator) or as the controlling cause (in the printer) of the movement of the 32 levers.

Slots in and projections on the grid bars and levers are aligned distinctively, as the tumblers in a Yale lock, to admit of encoding (for perforating) or decoding (for printing) only one coded character combination at a time.

Whether the grid's bars and levers are to be moved by hand, by solenoids, or by motor-driven cams, are details,[2] as are their configurations. The fact that five-unit perforation can be controlled by 32 levers suggested that reperforation could be similarly controlled—that the code bars which selected the typebars of a teleprinter could also (even at the same time) select the punch pins of a perforator for the purpose of duplicating at station *B* the tape existing at station *A*. Such a duplicate tape could be switched for use in onward transmission, saving the labor of repunching it from a keyboard.

When combined with a teleprinter typebar-platen mechanism which, at the same

[1] Parkington, E. L., Function Mechanisms of the Model 28 Teleprinter, *WUTR*, **10**, 7, 1956.

[2] Harrison, H. H., Developments in Machine Telegraph Systems and Methods of Operation, *J. IEE* (London), **68**, 87, 1930.

time that it reproduces a tape, records on it the actual letters and figures represented by the punched holes (*i.e.*, a translation of the code), the reperforating device is called a *printer-perforator*. If the reperforator is combined with a tape transmitter for the onward electrical transmission of its output, the device is called a *reperforator-transmitter*. A combination of all three produces a *typing-reperforator-transmitter*.

Start-stop printer-perforators receiving directly from an incoming line[1] for push-button switching are more complex and expensive than cross-office reperforators[2] which work only locally and in which the translating function is unnecessary.

The third essential instrument, besides tape perforator and receiving teleprinter, is the (sending) transmitter, whose five sensing pins test the passing tape for holes (*marking*) or the no-hole (*spacing*) condition and throw five contacts either to mark or to space for transmission of the proper signals to line.

The speed of a transmitter is controlled by its outgoing or cross-office circuit, that of a reperforator by an incoming or cross-office circuit. If the outgoing speed is less than the incoming, an accumulation of tape takes place between reperforator and transmitter. If the outgoing speed exceeds the incoming, the tape will become so short that it will tear or break—unless a device, known as an *autocontrol lever*, which rides the tape loop between reperforator and transmitter, renders the transmitter tape-feed sprocket temporarily inoperative until more tape is produced.

When a message has been completely punched up in tape, perforation ceases, the tape loop tightens, and the autocontrol stops transmission, leaving the latter portion of the message in storage. If an operator is punching the message, he will insert a sufficiently long succession of nonoperative characters to serve as a tape feed-out, so that the last intelligence character of the message will pass over the transmitter sensing pins. If a reperforator is punching the message, it must sense the same situation and automatically insert tape feed-out characters. This introduces certain equipment complexities and extraneous characters which can be avoided by pivoting[3] the transmitter in such a way that as the tape loop tightens, the transmitter will "climb" it and will continue to do so until the last intelligence character has been sensed and transmitted. The first character of the subsequent message is immediately transmitted in such a typing-reperforator-transmitter-distributor. As manufactured, this device also contains a code-reading stunt-box appliqué unit not unlike that of the type 28 teleprinter; hence it has become one of the more versatile building blocks of private-wire switching systems.

45. Repeaters and Regenerators. A repeater is essentially a back-to-back juxtaposition of a receiver and a transmitter, inserted into a line for the purposes of dividing its length for speed advantage and of boosting attenuated power. Vacuum tubes or transistors in amplifiers are basic to the repeating of carrier and other modern forms of telegraphy including the narrow band widths of submarine cables.[4]

The significance of logarithmic attenuation with line length (Sec. 9) is recognized in the optimum spacing of repeaters in a line. Dividing the length of line l in half by insertion of a mid-way repeater increases its speed S and therefore its capacity to carry traffic four times (*i.e.*, by the square of the number of sections). This principle is expressed in an early submarine-cable formula, $S = k/CRl^2$. Line l and G, being small, are neglected; C and R have their usual values in per-mile units, and k is a speed constant which pertains to the apparatus and method of operation of the circuit.[5] It is not always convenient or possible to divide a circuit with repeaters placed at

optimum points. In that event the slowest section will determine the working speed of the whole circuit.

Another function of a repeater is to improve signal-to-noise ratio (P/N) by supplying power gain at a point in the circuit where the noise level is low. The telegraph-cable sea-bottom amplifier[1] is so situated, at a point shielded from extraneous noise, where a lift in the signal level permits it to override interference picked up subsequently in an exposed portion of the line.

Table 6 shows typical repeater spacing in miles for various kinds of line. The effects of noise ratios are evident in the different levels of gain suiting noise conditions encountered in shielded cable and on exposed open-wire line.

Table 6. Typical Repeater Spacings

Type of line	Max frequency	Transmission loss per pair-mile, db	Repeater spacing, miles	Amplifier gain, db
Submarine cable	20.8 cps	0.054*	2,148*	57*
Single open wire, grounded	25 cps	†	250	†
Single open wire, grounded	60 cps	†	250	†
Multipair cable pairs	30 kc	2.5	18	45
Multipair cable pairs	60 kc	3.0	15	45
Open-wire transposed pairs	30 kc	0.15	150	22.5
Open-wire transposed pairs	60 kc	0.2	100	20
Open-wire transposed pairs	150 kc	0.3	60	18

Repeater spacing on coaxial cables, from 5 to 7 miles at 1 Mc to 2½ to 3 miles at 10 Mc. All distances representative, but latitude is afforded in practice.

* Distances and losses in nautical miles. Repeater spacing dependent upon geography. Total loss of 115 db divided between one submerged and one shore amplifier.

† Repeater spacing empirical.

The simplest amplifiers are those which repeat a received carrier envelope with its carried modulations intact. At carrier terminals and other traffic "bundling points," where circuits converge or fan out, the carrier has to be demodulated into either v-f groups, individual v-f bands, separated subbands, or single telegraph channels; and while some of these will be terminated there, others will be repeated into other carriers and some into circuit legs and loops (Sec. 31), either with or without regeneration.

Regeneration may be accomplished by tube circuits[2] or by mechanical means. The latter involve back-to-back receiving-sending apparatus, consisting of synchronous brush-commutator (rotary) distributors and (sometimes on the same shaft) outgoing brushes which re-create fresh onward signals from distorted incoming ones (Sec. 36). A lag is introduced between received and sent signals, producing an interval during which pulses are held in storage (commonly as charges on capacitors) so that irregularities in the line *east* will not be repeated into the line *west*. Capacitor storage can be employed in the extreme case where signals from the line east may be absent, because of trouble, for several minutes, yet upon restoration the repeater will be found to be in step (synchronized).

On grounded telegraph land lines or on local loops, operated at 66 cps or less, repeating of signals is achieved purely by relay circuits. Repeaters may be one-way or duplexed. Single-line (back-and-forth) land-line repeaters require special continuity-preserving circuits. These were once of considerable interest and importance but now are all but obsolescent in an age of one-way carriers and four-wire lines. Modern d-c repeaters feature full flexibility in relation to their duplexed or half-duplex oper-

ation, and as to the number of loops and lines which may be brought into network arrangements through the use of dummy circuits.[1] The most widely used repeater (other than the interconnection of carrier sections) is the half-duplex network repeater. The reperforator-transmitter-distributor combination is also, of course, a teleprinter repeater of a loose-coupled type.

46. Functionally Switched Equipment. Under this heading may be grouped a number of kinds of shared telegraph equipment which have the common feature of being somewhat detached from individual telegraph lines themselves but which are switched in and out of circuit in the routine of handling telegrams. The list includes concentrators, reading circuits, directors, allocators, load distributors, timers, sequencing equipment, line finders; busy signaling, alarm, and test equipment; code translators; numbering and time-and-dating machines; and bookkeeping and monitor printers. Some of these functions are described elsewhere (Sec. 34). The purpose of this section is to point out this similarity: that a restricted number of pieces of auxiliary equipment are required, by switching methods often automatic, to cover a larger number of connected items of apparatus or circuits in turn. The engineering determination of the number of ancillary pieces so required can be calculated according to the principles of probability applied to holding time and group efficiency (Sec. 33, references).

A manually operated switchboard involves obvious relationships, of the type mentioned, between the numbers of lines, of calls per unit of time, of terminal instruments, of multipled panels, of patching-cord circuits, and of operators. A telegraph-line *concentrator*,[2] similarly, may serve 400 tape-teleprinter tie lines by means of 11 rotary switches, 44 central-office receiving printers, and 15 operators. In each group of 50 tie lines (balanced as evenly as possible), the first 5 calls go directly through a secondary line finder to the lowest-numbered teleprinter not in use; the next three calls, if the first 5 teleprinters are found busy, go through second, then through first secondary rotary switches to the lowest-numbered idle teleprinter. Since the lowest-numbered idle rotary switch always answers the next call, the calls received during light traffic periods will be concentrated on a minimum number of adjacent operating tables. It is also provided that the loads allocated by the switching system will be equalized among the operators until the point is reached, on an increasing load, that an additional operator should be assigned.

As rotary switches cut themselves in and out of circuit in response to received calls, so do code *translators* required to convert tape-teleprinter signals for page-printer operation.[3] For example, they are required to count the number of characters arriving in message texts and, upon receipt of the first word space following the fifty-eighth character, to (1) stop the transmission, (2) delete the word space, (3) substitute a carriage return and a line feed, (4) reset the counter to zero, and (5) restart transmission. For most conversions the translator adds characters, hence is a loose coupler between received tape signals and sent page signals. Other land-line wire conversions consist in changing the coded symbols for period, comma, apostrophe, per cent sign, etc., on account of keyboard differences between tape and page transmission.

One stunt initiated by a tie-line translator is to switch the entry of a *time-and-date unit* at the termination of a telegram.[4] After supplying automatically a notation such as "135 PM SEP 26 56" a rotary switch device transmits a carriage return and eight line feeds to provide spacing between successive messages. In the same way that this time-and-date unit obtains its encoded information from its memory (which is kept

up to date by clockwork), so a numbering machine[1] encodes consecutive number information, for use on the line, which it obtains from its system of Geneva wheels and cams.[2] Like many computer devices which "adjust" new to stored information, the numbering machine's entry into an informational train is governed by a reading circuit, awaiting a "trigger" combination; and its exit (and reversion to original transmission) is in response to its own last functional operation.

CHAPTER 28

TELEPHONY

By H. A. Affel[1]

INTRODUCTION

A telephone system intended to serve many individuals is necessarily complex and requires consideration of many factors. It must first permit setting up rapidly an exclusive channel from one party to any one of a large number of others which are remotely located. It must provide signaling or ringing to arouse the attention of the second party. When the connection is established, it must enable a two-way conversation to be carried on with privacy and with reasonable naturalness, volume, and
Fig. 1. Elementary telephone system.

freedom from unwanted noise. At the same time, economics plays a part, for all this must be accomplished at a price the users can afford.

1. Telephone-system Elements. The function which ensures that telephone users are connected properly to each other is generally called *switching*. The function of providing adequate communication paths of satisfactory speech quality is called *transmission*.

An elementary system is shown in Fig. 1. It includes (1) the *telephone set;* (2) a *loop* circuit connecting each subscriber to (3) a *central office* where switching may be accomplished; (4) *trunk* circuits for interconnections between central offices.

[1] Bell Telephone Laboratories, Inc.

In telephone systems extending over wide areas, several intermediate switching offices may be involved in order to afford flexibility and permit the interconnection of users nationally as well as internationally.

Some of the transmission paths may be made up of open-wire or fine-wire cable conductors. This is generally the case in loop circuits. Trunks may also consist of such facilities or they may include various types of radio links with or without carrier systems, in which case several communication paths are derived from one metallic or radio circuit. The choice of the communication link between the points involved will depend on the length, the numbers of circuits required, terrain conditions, and many other practical factors.

The switching systems, to permit the interconnection between a user and any other user, may consist of (1) a simple *manual* system with operators at switchboards at the central offices or (2) one of several types of *dial* systems in which an operator or the user himself sets into motion the equipment which automatically selects the desired telephone. In 1956 over 80 per cent of the telephones in the United States were dial.

In what follows, the different aspects of telephone-system design will be outlined and typical equipment considered in principle. References are given to sources of more detailed information.

2. The Telephone Set. A telephone set must have a *transmitter* and a *receiver*. A simple one-way communication system may, as shown in Fig. 2, consist of a carbon-microphone transmitter in series with a telephone receiver and a battery. The microphone has a diaphragm on which voice waves impinge and, by its movement, varies the resistance of a mass of carbon granules. The receiver consists of an iron diaphragm actuated by an electromagnet with a permanent-magnet core, which responds to the current variations created by the microphone. The diaphragm thus vibrates and passes on, more or less faithfully, a copy of the sound waves impinging on the transmitter.

Fig. 2. Elementary telephone set.

But a practical telephone set must embody other features, such as two-way operation and ringing. More components are required. Refinements are also needed in the design of the microphone and receiver. A typical modern set is pictured in Fig. 3. The various components are all mounted in the base of the instrument. Its circuit, shown in Fig. 4, includes, in addition to a transmitter and a receiver, various capacitors, a transformer or so-called *induction coil*, a *bell* or ringer, as well as switches and certain nonlinear elements whose function will be described later.

Fig. 3. Typical dial telephone set, 500 type.

In most cases the battery is located in the central office and supplies not only the power to the carbon transmitters of many subscribers but also plays an important part in supervision. This is referred to as a *common-battery* system.

In some older telephone systems and for special circuits generally not involving a central office, the battery may be located at the telephone set. A ringing generator, called a *magneto*, is then usually provided. Turning a handle of this permanent-magnet a-c generator provides a source of fairly high voltage which is applied to the line and actuates the bell at a distant telephone set or operates a signal at a switchboard.

3. Transmitter and Receiver. The modern transmitter and receiver offer higher stability and fidelity of transmission as well as efficiency as compared with models of the past. The simple disk of metal used as a diaphragm in earlier instruments tends to have a fairly discrete natural period of vibration, around 1,000 cps. It functions with maximum efficiency at this frequency and with reduced efficiency at other frequencies. Thus the speech transmitted is distorted, unnatural, and not of highest intelligibility. In both the transmitter and receiver of the new instruments, the diaphragms are no longer simple disks of metal but are shaped and supported to perform their functions more like pistons without sharp resonances. The airspaces in the set are also carefully proportioned to play a part in the over-all response.

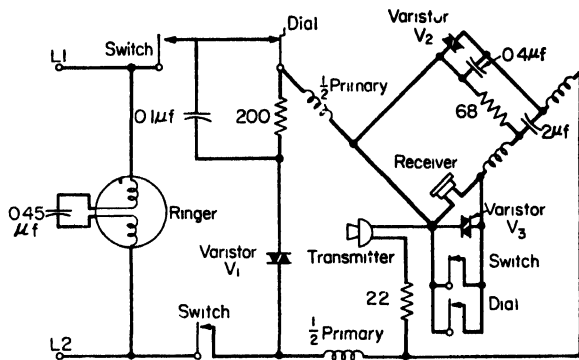
The carbon-granule transmitter has been greatly improved with time so that it is an instrument of comparatively high fidelity as well as stability and freedom from positional effects. Other types of microphones are, of course, feasible, such as an electromagnetic device like a telephone receiver in reverse, which was, indeed, Bell's original transmitter. Transmitters using piezocrystals of Rochelle salts or quartz, or condensers and other techniques, have also been employed for special purposes.

FIG. 4. Circuit schematic of 500D telephone set.

The carbon transmitter has, however, held its own in telephone practice because it is comparatively inexpensive and is actually a substantial energy amplifier as well as an acoustic-electric converter. Most other devices provide no amplification and are therefore comparatively inefficient. They generally require the interposition of amplifiers in the circuit.

The magnetic-acoustic design of the receiver has also been improved in recent years, and its efficiency as an energy converter is now fairly high, as well as reasonably uniform, over the required frequency spectrum. Cross sections of a typical modern transmitter and a typical receiver are shown in Figs. 5 and 6.

The transmission of conversational speech of reasonable naturalness and intelligibility requires the use of frequencies from about 200 to at least 3,000 cps. The gain in naturalness by transmitting lower frequencies and in intelligibility by transmitting higher frequencies is comparatively small and does not justify the considerably increased cost of the apparatus and system that would result from setting higher standards. The over-all frequency-transmission characteristics of a typical combined transmitter and receiver—sound path to sound path—are shown in Fig. 7 for loops of two lengths.

4. Speech Levels. In the case of the transmitter, when it is fed with a direct current of about 100 ma, the output of the telephone set is approximately −40 db below 1 volt across a 900-ohm pure resistance load with 1 *microbar*[1] input pressure at the lips of the talker. An average talker might develop a pressure of 20 db above 1 microbar, which would result in approximately −20 db below 1 volt or, roughly, 0.01 mw across a 900-ohm load. Loud talkers could readily exceed this value by a factor of 10, and the instantaneous peak voltages created might be another factor of 10 above the average.


[1] A microbar is 10^{-6} bar, which is equal to 10^{6} dynes per sq cm.

In the case of the receiver, 1 volt applied from a 900-ohm source will produce an acoustic pressure of about 30 db greater than a microbar at the ear of the listener.

5. Side Tone. The transformer or induction coil serves two main purposes: (1) by proper choice of winding ratios, it helps to establish optimum impedance relationships
Fig. 5. Telephone transmitter.
Fig. 6. Telephone receiver.

between the different elements of the telephone set and the line; and (2) it provides a degree of directional selectivity and tends to lessen the sound which returns through the receiver to the ear when speaking into the transmitter. Thus it minimizes the *side tone* when using the telephone set.

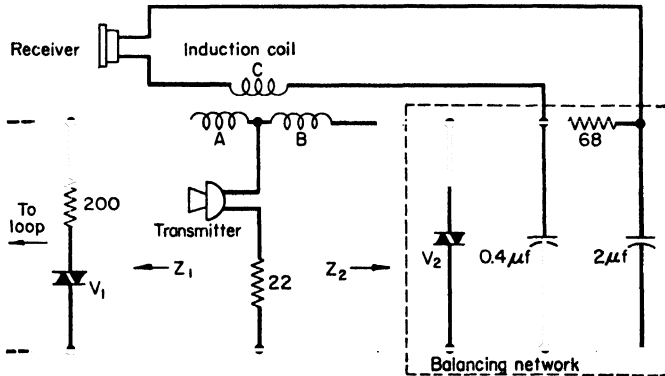
Excessive side tone is undesirable because it tends to discourage the talker from speaking sufficiently loudly into the transmitter. Room noises reaching the transmitter are also a possible source of annoyance. If the side tone is too great and there is an acoustic path between the receiver and the transmitter, either through the air or perhaps through the handle on which both are mounted, a feedback path may be established and sustained howling or singing set up.
FIG. 7. Transmission characteristics of 500D type telephone set.


FIG. 8. Transmission circuit of the 500D telephone set showing side-tone balance.

The function of the induction coil in reducing the side tone can best be understood by reference to Fig. 8. It will be noted that the transmitter causes currents to flow through windings A and B, the former passing to the loop circuit and the latter into a *balancing network* whose impedance simulates that of the loop–central-office circuit. The A and B windings are arranged to have opposing effects on the core, and the C winding to the receiver therefore receives a minimum of voltage when the transmitter is actuated. Speech currents received from the central-office–loop circuit are, how-

ever, effectively transmitted directly from winding *A* into *C* with only a minor effect from the portion of the circuit through winding *B*.

6. Equalizer. Another feature of the type of modern telephone set shown in Fig. 8 is the *equalizer*. This consists of a resistor and nonlinear element whose function is to adjust the efficiency of the transmitter and receiver so that, if the telephone set is located at a considerable distance from the central office and has a higher-resistance loop circuit, its efficiency is greater than that of telephone sets nearer the central office. Thus the spread in effective transmission between different users is held to reasonable limits.

The nonlinear element is a silicon carbide varistor whose resistance decreases as current flowing through it increases. Thus, in a low-resistance loop, where the battery current is greater than in a high-resistance loop, it provides a greater shunting of the transmitter and receiver, and increases the loss in the circuit. There is also a varistor in the line-balancing network, whose effective resistance varies with the length of the loop. This tends to stabilize the balance and keeps the side tone from becoming too high for certain loop conditions.

7. Supervision. The telephone set commonly includes a *switchhook* which, among other things, closes the battery circuit when the handset is removed from the base. This powers the transmitter and actuates a relay and switchboard lamp at a manual central office to notify an operator that the telephone subscriber wishes to place a call. In the case of a dial system, the relay connects the user to a network of equipment which, like the operator, receives information about the called party that the user dials. The dial provides a means for sending accurately spaced (10 per second) pulses over the battery circuit to the central office. The dial functions are further discussed under Automatic Switching.

The calling signal is generally a bell with a polarized electromagnet structure whose hammer strikes a pair of gongs at each alternation of the ringing current. This is commonly 20 cps, as transmitted from most central offices. The set shown in Fig. 3 also has a means whereby the user can adjust the loudness of the bell.

The matter of ringing and supervision is complicated in the case of *party-line* service, where up to four and, in rural areas, sometimes more telephones are bridged on the same loop circuit. In some rural cases, ringing is still on a code-selection basis in which the bells at all parties ring for all calls. However, in most common battery-exchange areas, the ringing is selective and the bell rings for only the called party. This is usually done by making use of ground-return circuits provided by the two wires, also applying polarized pulses to obtain a total of four different combinations of ringing power. Gas-filled rectifiers are used in this connection in some telephone sets. In other selective-ringing arrangements, tuned-reed relays, responsive to particular ringing frequencies, have been employed.

8. Speakerphone. A comparatively recent innovation in telephone sets is the *speakerphone* or "hands-free" set in which a transmitter is mounted separately or in the base of the set and the receiver consists of a small loud-speaker which is located on the desk or table at some distance from the transmitter. Since both the transmitter and loud-speaker must include an amplifier to give them greater over-all efficiency, there is danger that the feedback path between the transmitter and receiver may provoke howling or singing—or, if not sustained singing, hollow-sounding speech.

Such a speakerphone set can, under most conditions, give hands-free communication if the proper precautions are taken in setting it up and adjusting the sensitivity of the transmitter and receiver. The acoustic characteristics of the surroundings also play a part. The most advanced designs of speakerphone systems have automatic voice-operated amplification control to minimize the feedback problem and ensure satisfactory operation under all circumstances.

9. Hard-of-hearing Set. Another auxiliary feature is included in a special set for hard-of-hearing individuals in which an amplifier is connected in the receiver circuit and mounted in the base, with the degree of amplification controlled by a knob operated as desired. The amplifier consists of a transistor in a simple circuit powered by

1 or 2 ma of current taken from the office common-battery supply which also actuates the transmitter and provides supervision. It seems probable that transistors will play an increasing part in the functioning of future telephone systems.

There are also available two modifications of the hard-of-hearing set. The first of these is intended for use in locations which at times are extremely noisy. This includes a push button on the set which, when actuated in an emergency, adds a substantial amount of amplification in the receiver circuit, at the same time cutting out the transmitter.

The other modification is intended for people whose speech power is greatly impaired. In this case, the amplifier, otherwise connected in the receiver circuit, is connected in the transmitter circuit to increase the volume which passes on the line. The amplifier is not used, of course, when the telephone is spoken into by a person with normal speech volume, as serious distortion would result from overloading.

10. Telephone-set Switching. Telephone sets can be provided with a limited number of keys or push buttons which permit the set to be connected alternately to different loop circuits, or for intercommunication with a limited number of other sets in the same office.

11. Recording and Answering. Recording and answering devices have been made available to function in the absence of a user. In general, these devices, installed on the user's premises, respond to an incoming call and play back a previously arranged recording, telling the calling party that the called party is absent and that a short-period message can be recorded if the calling party will dictate it. Or the responding mechanism may simply give to the calling party a more extensive message, not expecting him to dictate anything.

These devices consist of an association of relays, amplifiers, and either magnetic-tape recorders or, in some cases, mechanical-disk recording of the phonograph variety. A sketch of a typical recorder answering device is shown in Fig. 9.
FIG. 9. Telephone answering set.

Another form of recording instrument is intended to be connected to the circuit and is capable of recording both sides of lengthy conversations between two telephone parties. If a record of this kind is to be made, the regulations of the Federal Communications Commission require that in some way both parties be made aware of the fact that the conversation is being recorded. This function is carried out by an attachment provided by the telephone companies, a *recorder connector*, which, every several seconds, applies to the line circuit a short spurt of 1,400-cycle tone of moderate strength. This has caused it to be referred to frequently as a "beeper" phone.

12. Sound-powered Telephone. For some special short-distance applications, particularly in the military field, use has been made of so-called sound-power telephone. These consist of electromagnetic devices which are like an efficient telephone receiver and can be used as either a transmitter or a receiver. Frequently two are mounted on the same handle, as in an ordinary handset. They have the advantage that, since the transmitter is a sound-electric converter, no batteries are required. In some cases, this provides a desirable element of reliability.

They have the disadvantage that, as a transmitter, the electromagnetic converter is

comparatively inefficient as compared with a carbon transmitter with battery. Therefore, they can be used over only short distances if no amplifiers are provided. The transmission distance using ordinary small conductors may be of the order of a mile or so compared with 25 miles or more for a carbon-button transmitter set. The exact comparison would, of course, depend on the size of conductors provided and the comparative line and room noise where the devices were used.

13. Protection. Close to where the user's loop circuit enters the premises, a *protector* is customarily installed to minimize the hazard to the user, the premises, and the telephone equipment in case the outside wires are struck by lightning or perhaps become crossed with a power line.

A protector basically consists of a gap between two carbon blocks having a separation of a few mils. Such gaps are connected between each line wire and ground. The most recent type of telephone protector, as shown in Fig. 10, consists of carbon block electrodes in a metal cap which, in turn, is screwed into a well containing a spring-loaded platform. On short-duration surges, arcing takes place only between the
FIG. 10. Details of the 98A protector.

carbon blocks and the device returns to an open-circuited condition. However, on sustained arcing sufficient heat is developed to melt the alloy spacer which allows the spring to push the carbon blocks up into the well until the metal platform contacts the rim of the metal cap. Thus a low-resistance path to ground is established that is capable of carrying considerable sustained power current.

Some older-type protectors, which are still in use, also included the feature of providing a permanent low-resistance path upon experiencing a sustained flashover, but in this case, in general, two low-current high-voltage fuses were included in series with the two conductors between line and carbon blocks. The fuses would open the telephone circuit by melting the fuse wire and relieve the carbon blocks of the load of the sustained power currents. The newer protector of Fig. 10 has sufficient current-carrying capacity that, in general, the series fuses are not required.

In central offices, *sneak current* devices called *heat coils* are frequently used in addition to protectors. Heat coils are connected on the office side of the protectors and operate on small currents through the equipment to ground that may occur at voltages below the operating value of the protectors.

SWITCHING—GENERAL

It requires no stretch of imagination to picture a telephone system of many users in which each user is provided with an independent circuit to every other user, and a multipoint switch by which he may establish a desired connection at will. The com-

plexity and cost of such a system would obviously increase at a much greater rate than in direct proportion to the number of users and would soon exceed reasonable bounds. The efficiency of use, that is, the percentage of time the various interconnecting circuits were employed, would average very low in such a system.

The efforts of a telephone systems' designer are directed toward minimizing the number of interconnecting circuits, hence using them more efficiently. This calls for the establishment of central offices or other intervening switching points which are joined together by trunk circuits.

The telephone user originates the switching action. In manual operation, raising the telephone instrument places the user in contact with an operator at a switchboard in a central office to whom he gives the information by voice. In an automatic system the action of dialing passes on the called number to the equipment in the central office.

14. Switching Functions. Certain functions are required in a central office, either manual or automatic:

1. Means for identifying the calling line when the user raises his set from the switchhook
2. Means for making a connection to the calling line
3. Means for picking out an available transmission path to the called party, who may be connected to the same switchboard or to some other distant switchboard reached over one or more trunk circuits
4. Means for determining whether the called line is already in use
5. Means for signaling at the called station
6. In many cases, means for recording the location and duration of the call
7. When the parties at both ends terminate the conversation and hang up their sets, means for restoring all circuits to a state of readiness for other calls

In the case of a connection from one part of the country to another passing through several switching points, the design of the system must, as noted in Sec. 37, ensure that the over-all transmission loss, when the several links are connected together, does not exceed a reasonable value.

Also, the systems engineer must be certain that sufficient trunks are provided between switching points so that, in so far as economically practicable, the demand during the busy hours will not tie up all the available facilities and cause excessive delay in establishing a connection. This requires traffic studies by specialists who, with statistical information and probability theory plus experience, are able to predict how many trunks are needed between particular locations.

Included in such system design is, of course, the provision for alternate routing of connections in case of failure of a link in the preferred routing of a call or where the facilities are temporarily overloaded. This can be accomplished to a certain extent by operators in a manually operated system but, with an automatic-switching system, this function is carried out in a matter of seconds.

15. Private-branch Exchange. In the over-all switching plan, a loop circuit generally connects a user's telephone set to a central office where the first step in switching takes place. However, in many situations, as in organizations having large numbers of telephones, the first switching point may actually be on the premises of the organization in the form of a *private-branch exchange,* commonly termed *P.B.X.*

All the individuals' telephones are connected to this P.B.X. From it to a central office a certain number of trunk circuits are provided, substantially less in number than the total number of telephones connected to the P.B.X. Such a P.B.X., which may be either manually operated or a dial system, also permits intra-P.B.X. calling between the various individuals connected to the P.B.X. Thus the trunk circuits to the central office are used only on outgoing or incoming calls. P.B.X. installations of several thousand telephones are not uncommon in many large organizations, although they range upward from a comparatively few telephones in the case of a small organization.

16. Line Concentrator. Another primary step in switching may be provided by recently introduced equipment termed a *line concentrator.* Where there are many

unrelated users in an area located at some distance from a central office, instead of providing individual line circuits to the central office, such a concentrator may be installed near the group of users. It is an automatic-switching device into which all the users are wired, and which provides a limited number of trunks, say about one-fifth of the number of users in the group, between the concentrator and the central office. Thus it saves mileage in the loop circuits involved.

The relay equipment in the line concentrator, in conjunction with coordinating control equipment at the central office, automatically picks out an idle trunk when a user wishes to place a call. A concentrator can be considered as a sort of elementary central office or perhaps better as an extension of part of the central-office functions to a remote location. It is evidently also related in function to the automatic P.B.X., although it does not ordinarily provide means for the connected users to talk with each other without employing the trunks to the central office.

17. Components of Switching. Just as in transmission, there are various *devices* to carry out desired functions, such as inductors, resistors, and capacitors, so the switching designer also has various components at his disposal. These are mainly variants of the simple switch, *i.e.*, a means for making and breaking a circuit.

Some of these are, of course, quite familiar, such as the plug and jack. Where switching of one circuit is required to any one of a number of others, an operator may handle a flexible cable, termed a *cord*, on the end of which is mounted a *plug*. This may be thrust into a *jack* and thus make connections involving from one to three wire conductors. These are referred to as the *tip*, *ring*, and *sleeve* conductors. They derive their names from their position on the plug. The jack has springs which contact the tip, ring, and sleeve sections of the plug when the connection has been established.

Where a number of jacks are mounted together on the same structure, this is a *jack strip*. Many jack strips in close proximity provide a *jack field*. In turn, together with other equipment, they may make up a *manual switchboard*.

The other equipment on a switchboard consists mainly of *keys*. These are switches capable of being manipulated by an operator to make connection between certain desired portions of the circuit, including the cord. A key may have many springs or contacts. The key commonly used has an intermediate position as well as left and right positions to carry out its functions.

FIG. 11. Typical multicontact wire-spring relay.

A switchboard may also have small *signal lamps*, usually mounted close to jack positions, to indicate when a telephone user, whose circuit connects to a particular jack, wishes to alert the operator.

18. Relays. Perhaps the most important basic device of switching, both manual and automatic, is the *relay*. There are literally thousands of different types of relays, some, of course, differing from one another only in the number of contacts or *springs* which are affected.

The type of relay currently being applied in large numbers is shown in Fig. 11. This is a so-called *wire-spring relay*. It derives its name from the fact that the contacts are at the ends of springs of highly resilient wires. These wire springs take the place of flat springs which made up the structure of some earlier types of relays. The wire-spring relays have advantages in speed, sensitivity, and economy of manufacture.

19. Switching Systems. In automatic switching there are various special forms of switch-relay construction, for example, the *step-by-step* switch which appears in many different specific forms. In general, a step-by-step switch functions, as the name implies, to step a moving contact from one point to another each time a pulse is

received from the line circuit. Sometimes such step-by-step switches are arranged to select the proper contact point on a two-dimensional basis. The stepping mechanism first proceeds to find the necessary location in a vertical column and then moves at right angles to find one of a number of contacts across the row. Figure 12 shows, schematically, a particular form of step-by-step switch.

Another special switch connector is the *crossbar switch.* In this switch, shown in Fig. 13, a connection is made at a crossing of so-called *bars* in a rectangular-coordinate system. The bars in one coordinate are operated by a series of relays; correspondingly,
FIG. 12. Operation of step-by-step selector.

the bars in the other coordinate are responsive to other relays. Such a crossbar switch may make a connection at any one of 200 cross points, where there are, in effect, 10 relay bars in one and 20 in the other coordinate. A number of different cross-point connections may be made simultaneously. Each connection may involve two or more contacts.

Another common adjunct of all telephone central offices is the distributing or *cross-connecting frame,* into which all the circuits entering the office appear on *terminals* or lugs. Nearby, on other terminals, also appear all the circuits leading to switchboard or dial-switching equipment in the office. This permits running cross-connecting wires between the sets of terminals to tie together the office equipment and the line circuits in order to carry out certain layout arrangements. They may be changed from time to time by simply removing the old and attaching new cross-connecting wires. The whole arrangement is a means for providing flexibility and enabling the telephone office to meet new or changing service requirements.

20. Electronic Components. Even a brief summary of switching components would not be complete without mention of various electronic devices which promise to play an important part in switching systems of the future. One or two electronic devices have received application in the past, such as the cold-cathode gas tube which permitted eliminating the polarized relay in four-party ringing circuits.

Gas-filled or vacuum tubes can obviously be used in many types of circuits demanding fast relay-type action. The newer semiconductor devices, such as transistors and diodes, show great promise because of their small size, low power requirements, and speed of operation as compared with electromechanical devices, like relays.

For the storage of digital switching information, certain cathode-ray-type structures can be employed. *Magnetic-tape* or drum devices have been used experimentally. *Magnetic-core* devices, employing alloys of various types, including *ferrites*, have also been tested, as well as devices employing *ferroelectric* materials, such as barium titanate. It seems likely that switching systems of the future will be revolutionized in details of construction even though the broader principles of operation may continue to follow current practices.
FIG. 13. Partial perspective of crossbar switch with 10 vertical units. Electromagnet *A* pulls projection *B* which tilts the horizontal bar so that a wire *C* projecting from the bar into the switch mechanism is raised into position. Magnet *D* now operates and pivots the vertical bar *E* inward. Bar *E* pressing against wire *C* closes the contacts and completes the connection.

21. Telephone-office Power. To operate the various equipments in a telephone office requires substantial sources of power, usually direct current. It is essential that they have great reliability. Storage batteries of substantial capacity are provided, and these are kept on floating charge through rectifiers or motor-generator sets driven from commercial power sources. Direct current at 48 volts is required in the greatest quantity, although other voltages up to 130 d.c. are also needed for special purposes, such as the plate battery supply for vacuum tubes. The storage batteries provided are usually of substantial capacity to take care of contingencies and in ample time to permit maintenance attendants to reach the office to start an emergency gasoline or diesel-engine set. Each telephone office is equipped with one or more such motor-generator sets which can carry the full office load indefinitely in case of a commercial power failure.

22. Manual Switching. The switchboard in a typical central office makes accessible to a single operator several thousand individual jacks for the various subscribers'

lines, as well as other jacks which connect to other central offices and to distant switchboards.

In an office of some size, these jacks appear in multiple at several operators' positions. Each jack has associated with it a signal lamp which lights on an incoming call. Thus several lamps in the multiple positions light simultaneously, and the first available operator seeing the light inserts the plug of her *answering cord* into the particular jack, whereupon the line lamp automatically goes out at all multiple positions. Figure 14 shows a cross section of a manual-switching-cord circuit. After the operator has
FIG. 14. Cross section of typical manual switchboard.

received the desired number from the user, she plugs the *calling cord* into the jack of the called telephone. An operation of the key switch applies 20-cycle ringing current to sound the bell of the called party.

In the case of larger central offices, the functions of receiving the calling signal, making contact with the user, and completing the call to another telephone in the same office are usually divided between two switchboards—the so-called *A* switchboard and *B* switchboard. The *A* operator, who has accessible perhaps 1,000 or 2,000 jacks, answers the call and passes on the called number to the *B* operator, who is able to reach directly as many as 10,000 or more jacks on the *B* switchboard.

If the called party is in another central-office area, the operator plugs the calling end of the cord into an interoffice trunk jack which signals another operator at a *B* switchboard who, in turn, makes the connection through her calling cord to the called party.

In the case of a call to a distant point, the initial operator plugs the calling cord into the jack connecting to another switchboard particularly adapted for handling such calls, and the telephone user gives the special operator further information about the call. This operator makes a record of the information and completes the call through other jacks connected to remote points. The call may be routed through other intermediate offices, since obviously all such switchboards do not have immediate access to other similar switchboards in the country. The originating operator also stamps on a ticket the exact time the called party answers and also when it is completed as indicated by the extinction of a light when either party has disconnected.

23. *Toll Dialing.* In the United States a large percentage of the intercity connections are now made automatically by an operator who dials the distant point, and the intermediate offices are automatically selected by the mechanism. In a growing number of areas in the United States, a user may dial another telephone directly in certain other areas without the interposition of any manual operator. The trend of development and application is definitely in the direction toward a time when all telephone users will be able to dial directly most telephones in any section of the country. Additional equipment is required for this purpose and it will be a few years before the dialing of long distance as well as local connections is universal. Of course, person-to-person calls will always require the assistance of an operator.

In anticipation of this eventuality, the United States is divided into areas each of which has a three-digit designation, which will be dialed first in connection with a long-distance call. Also, all users' telephone numbers are to be placed uniformly on a seven-digit basis, *i.e.*, two digits for the first letters of the central office, a third digit for the central-office number, and four digits for the individual telephone number. Thus, for example, a call from some distance to a Chicago number might be dialed 312 (area designation), then BUckingham 1-6200.

AUTOMATIC SWITCHING

In automatic-switching systems, functions otherwise performed by an operator are all automatically controlled by the dial impulses sent out from a telephone set. In current practice there are two important types of automatic systems: (1) the so-called *step-by-step* system and (2) the *crossbar-switching* system, both of which systems derive their names from the basic types of switches which are used to perform the operations.

The step-by-step system is becoming more and more limited to application in cases involving a small or moderate number of subscribers. It is a system of comparative simplicity, but large amounts of equipment are used exclusively for the duration of each call.

In the case of the crossbar system, which is a so-called common-control-type system,[1] much equipment of considerable complexity is involved momentarily in setting up a call, but it is not held for the duration of a particular call and so is available for setting up other calls. This general philosophy of design makes for efficient and speedy operation in large central offices.

24. Step-by-step Switching. The functioning of a step-by-step switch has been shown in Sec. 19. When a user picks up a telephone, the fingers of a particular step-by-step selector switch, functioning as a *line finder,* sweep through different lines and pause on the particular line where the telephone set has been lifted. Thereupon a dial tone informs the user that it is proper to make the call.

The circuit from the user is then connected to the fingers of the *first selector.* This selector, which is shown in Fig. 15, steps up the contact level corresponding to the first dialed letter or digit. The 10 terminals on this level lead to other selector switches. The selector automatically rotates across the horizontal terminals until it finds an idle terminal which leads to a second selector. As the second letter or digit is dialed, the *second-selector* switch steps up to the corresponding level. The same general process,

[1] An earlier so-called *panel* switching system, still used to some extent, also has common-control features.

in turn, leads to a third selector which completes the connection to a trunk to the desired central office in the area.

A similar step-by-step selection process involving three switches then takes place at the central office of the called party. At this point, with the numbers whose first two digits correspond to the numbers of the particular party dialed, the second selector rotates until it finds an idle terminal when a connection is made to the *connector switch.* The connector switch steps up to the level corresponding to the third dialed particular number and pauses until the fourth digit is dialed, whereupon it rotates the contact corresponding to the fourth digit, which is presumably the terminal of the user's line desired.

In the case of both the connector and selector switches, there is actually a second finger and set of contacts which operate mechanically in parallel with the talking-path contacts and which are used in connection with determining whether the called line is
FIG. 15. Path of a call in step-by-step system.

busy or idle. When the finger has reached the terminal of the desired line, an automatic relay arrangement applies ringing current in timed spurts until the telephone is answered or the calling subscriber hangs up.

This description has thus far traced a call to a party in another central office. Actually, in the general case, with seven-digit subscribers' numbers which are now standard, a call to a party in the same central office is carried out by the same selection process.

In simple P.B.X. step-by-step switchboards, it is possible to get along with fewer steps where only a relatively few lines are involved.

25. Crossbar Switching. Crossbar switching differs chiefly from step-by-step in that the equipment does not respond to step-by-step signals as the successive digits are dialed. In a certain sense, it functions more like an operator who receives the call and then routes it in accordance with a knowledge of the circuits and circumstances involved.

There are two main divisions of equipment in a crossbar-switching system, which have different functions: (1) the control equipment which establishes talking paths by causing the proper switches to operate; (2) the switching network, mostly crossbar switches, through which the talking paths are set up.

To begin with, a group of crossbar switches can be used to make up a **crossbar-switching network.** As shown in Fig. 16, each small square represents a switch. A group of eight switches represents those which might be mounted in a frame in a central office. To simplify the drawing, only two lines come from each side of a switch, although in an actual switching central office, 10 lines would extend from each. The switches are evidently interconnected in a definite geometric pattern. If, for example, it were desired to connect points A and B, one could choose either of two routes through the network. In a central-office system, where 20 vertical-unit crossbar switches, such as previously pictured, are interconnected in a similar pattern, there are 10 possible electrical paths between A and B.

Fig. 16. Basic switching-frame arrangements in crossbar system.

A typical crossbar central office of 10,000 lines contains 1,800 crossbar switches and some 70,000 relays of all types.

26. Control Equipment. Figure 17 shows diagrammatically in more detail what happens in a No. 5 crossbar system. When the user picks up a handset, he is actually connected to a crossbar switch in a *line-link frame* of the switching network. In a fraction of a second a so-called dial-tone *marker* circuit is signaled. Quickly thereafter it sets up a connection from the calling line to an *originating register*, whereupon the marker is disconnected to handle other calls. At this point dial tone is transmitted to the telephone caller, who then dials the number desired.
Fig. 17. Path of call in crossbar system.

The marker is a complex arrangement of relays which acts as the dispatching brain of the equipment. It "marks" points in the switching network (like A and B in Fig. 16) to which calls must go and selects and establishes paths between these points. This complex operation is performed by the marker within ½ sec per connection.

The originating register is a sort of telephone operator who passes back dial tone instead of saying "Number, please" and remembers the dial numbers, using relays and switches instead of a human brain. *Incoming registers* perform the same function for calls from other central offices.

When the last dialing impulse has been received, the originating register connects to an idle completing marker and transmits the number desired to it. The first three digits of the number, the so-called office code, tell the marker the name of the office called. If the called number is in another central office, the marker disconnects the originating line from the originating register, connects the proper *sender* to the proper outgoing trunk, and connects the originating user's line to the trunk through the *line-link* and *trunk-link frames*. The sender then transmits the number desired to another central office.

In the second central office, an incoming register records the number from the distant sender, after which it connects to a marker. The marker receives the number from the register. The marker now locates the called number in its office. To do this it checks the *number-group frame*. This is a mechanical telephone directory which knows the number of every telephone in the central office—knows to which terminals, on which line-link frame, each telephone is connected and is prepared to give out this information any time it is asked by the marker.

The marker obtains the location of the number, the right line-link frame, the crossbar switch, etc. Then the number-group frame and incoming register are dismissed by the marker, which now connects the incoming trunk to the called number through a trunk-link frame and line-link frame. Since the connection is now complete, the marker disconnects itself and goes about other business. The incoming trunk rings the called line and the call is complete when the called party lifts the receiver. At this time the users are connected only through the line-link frames and trunk-link frames in their respective central offices.

Senders are required in handling calls to other offices. Senders transmit numbers in special codes other offices are set to receive. Different types of senders are provided to transmit signals to different types of central offices, such as step-by-step, crossbar, and manual offices. In step-by-step connections, the codes are generally in a decimal system. If a different code is required, the senders and other switching equipment are prepared to translate from decimal to this code.

As simplified previously, the line-link frame is a unit consisting principally of crossbar switches to which telephones are connected. The line-link frame is the first link in the call from the user and the last also, since all telephones are connected to a line-link frame. A trunk-link frame is a unit to which trunks in the central office are connected. A trunk which begins and ends in the same central office is called an *intra-office trunk*. Lines or circuits which lead to or from other central offices are generally called *interoffice* trunks.

It is evident that in detail the equipment of a dial system is extremely complex—beyond the scope of this handbook to describe in detail. For example, a marker has about 2,000 relays. Fortunately, the marker as well as other office equipment which is relatively complex is not needed during the whole period of the conversation. They carry out their function in a fraction of a second, and the whole call is put through in considerably less time than it takes to describe even the major steps in it.

The functions carried out by the various major elements in the crossbar-switching system may eventually be carried out by electronic devices, such as transistors, diodes, electromagnetic memory units, and cathode-ray memory tubes. The chief advantages of doing this electronically are still greater speed of operation, smaller space for the equipment, and perhaps somewhat lower cost.

27. Intercity Switching. In a general sense, the functioning of intercity switching carries out more specifically and in greater detail the type of switching operation which starts with the originating office. However, as noted previously, three more digits are needed to direct the call to the particular region where the call is destined. Crossbar switches, relays, and, to some extent, step-by-step switches make up the switching equipment.

An important additional unit in the intercity-switching terminal is the *card translator*. This has some functions not unlike the number-group frame. It is a mechanical directory of routes which the call must take in passing from one area to another.

The information in this device is carried on large metal cards, as the name implies, which are punched in various ways. The punched holes permit light to pass through or be obscured, and these light beams actuate phototransistor units which, in turn, give the switches the information desired.

Intercity calls may be dialed by the operator directly if the called telephone is in a dial area or, as noted previously, in the case of certain selected areas, station-to-station calls may be dialed by the originating user.

28. Message Accounting. In the case of certain manual systems, where the accounting basis requires it, a *message register*, which is a counter associated with each user's line, is actuated each time the operator concerned with a call presses a register key. This enables the telephone company to keep track of the number of calls. In a dial system there is a similar arrangement which, in its elementary form, not only registers calls in the immediate user's area but also, if necessary, registers two or even more call units each time a call is made to extended areas which are a greater distance from the user.

More complex equipment is being installed, particularly in larger cities throughout the country, which is termed *automatic message accounting*, or A.M.A. In this equipment, information is registered by punchings on a tape for each call. This information includes the calling number, the called number, and the date and time of the beginning and end of the call. This accumulated tape for an office may be collected at periodic intervals and processed through automatic computing machinery which finally makes out a statement which can be billed to the telephone user. The tape processing and billing can be carried on at some central accounting center for a large city where information from several central offices is collected.

In some cities the automatic-message-accounting equipment associated with several central offices is located at the same point and the tape records are thus conveniently available for further processing. This is termed centralized A.M.A., or C.A.M.A.

TRANSMISSION—GENERAL

To enable persons to carry on a satisfactory telephone conversation depends on a good many factors. Some of these are under the control of the telephone-system designer; others are a function of the user's habits, such as:

How loudly the talker speaks, and how he holds the transmitter with respect to his lips

The noise conditions at the listener's telephone location

How good the listener's hearing is and how he reacts to different volumes; also how he holds the receiver with respect to his ear

29. System Transmission Parameters. Of those items which are under the control of the designer, the telephone set, as already discussed, is very important. This includes the conversion efficiency of the transmitter and receiver, their frequency transmission characteristics, side tone, and other practical factors.

The communication engineer may select the type of telephone set best suited to the situation at hand, and the voltage and battery current supplied to the set can, if necessary, be chosen to control the efficiency of the transmitter. Economics and the need for standardization in a system of some magnitude must also be considered.

The measurement of the over-all acoustic performance of a telephone circuit from transmitter input to receiver output presents some problems in practical application although, currently, some consideration is being given to its possibilities.

Hitherto, the transmission design and maintenance of a telephone system have usually been judged chiefly by the performance of the electric circuits between the two ends of a telephone connection.

The most important considerations are:

1. The *attenuation* of the path over the range of frequencies in the speech band, roughly from 200 to at least 3,000 cycles.

Related is the *linearity* or load-carrying capacity of the path. In effect, this is the

change in attenuation of the path with varying powers. If there are nonlinear elements in the path or if the power applied exceeds reasonable limits, the input-output power relationship will not be proportional. Distortion of the wave form of the speech currents will result. Frequencies other than those applied to the circuit will be created to degrade the speech.

A fair amount of nonlinearity can be permitted in a circuit carrying only a single speech channel. Where unwanted frequency components can be kept below 30 db or so of the wanted currents, the situation is usually tolerable. However, in a carrier or radio circuit having more than one channel separated on a frequency basis, nonlinearity in common equipment produces intermodulation between the different channel frequencies. This results in noise or cross talk. The linearity requirements in such multiple-channel systems are considerably more severe than those of single-channel systems.

A practical measure of the linearity of a circuit is to apply, simultaneously, currents of more than one frequency of the desired level and measure the intermodulation frequency components produced.

2. The relative *phase change* of the different frequencies in the speech band. In the ideal case the phases of the different frequencies in the speech band should be such as to establish the same wave form as originally transmitted. For ordinary telephony this factor can, however, usually be disregarded.

3. The amount of unwanted current or *noise* which reaches the circuit from external sources. In its effect on the listener this is added to the room noise which he experiences while using the telephone. The absolute amount of noise can be serious but is usually less important than the noise relative to the average speech power. The character of the unwanted noise is also important in determining the severity of the disturbance.

If the unwanted sounds consist of cross talk from adjacent circuits or other sources, *privacy* is also a consideration. In the general case cross talk cannot be permitted to be intelligible to a user. This means that it must be kept to less than the order of 60 db below or one-millionth of the average speech power. The magnitude of the other noise on the circuit is a factor in determining the exact amount of cross talk permissible.

4. The *impedance* of the circuit as determined by the electrical constants of the circuit. In a uniform wire circuit, it is the *characteristic impedance*, or the impedance of such a circuit of infinite length. Of course, a radio system or other equipment which may form part of a long circuit will also have an input and output impedance determined by its components.

The influence of impedance on system performance varies. It may, in the case of a wire circuit, be related to the attenuation of the circuit. It is of prime importance in connection with the operation of repeaters in two-wire circuits and in the junction of two-wire and four-wire circuits.

It always is an important factor when circuits or equipments of different types are joined together. In joining circuits it is generally desirable that they should have the same impedance. Failure to match impedances may result in increased circuit losses by reflections. If there is not a reasonably smooth impedance match throughout the effective frequency range, there may also be amplitude-frequency distortion to impair speech quality. Echoes may also result.

30. Transmission Measurement. The evaluation of telephone transmission imposes problems that do not exist in the case of power transmission, where it is comparatively simple, with a voltmeter, ammeter, or wattmeter, to make a precise measurement at any point in the circuit under conditions of essentially constant frequency.

In the case of a telephone transmitter, both the absolute power and frequency vary from instant to instant. The average a-c power which flows from a transmitter with strong talkers is of the order of $\frac{1}{10}$ mw if integrated over a long period. With a weak talker the power may readily drop to one one-thousandth of this figure. Instantaneous peaks of power may exceed ten times these figures. Correspondingly, the frequencies may vary instantaneously throughout a range from 200 to over 3,000 cps.

With a knowledge of the characteristics of the transmitter and receiver, it suffices, in general, to treat the engineering aspects of telephone transmission by a consideration of the *relative* power rather than absolute power. This means paying attention chiefly to the attenuation of the circuits—for the frequency range of interest.

In the case of wire circuits of uniform construction, it is possible to compute the loss of the circuit from a knowledge of its electrical constants, as discussed further under

Wire Circuits. It is possible in general to determine, by estimate or measurement, the characteristics of any of the other elements that may make up a long telephone circuit.

31. Transmission Units, Db, Dbm, VU. Such computations or measurements are commonly expressed in *decibels*, which has the advantage that the over-all attenuation of a circuit made up of various links can be determined by the simple addition of the decibel losses of the component sections. In addition, there is evidence that, in its effect on the ear, relative loudness is judged roughly in proportion to the logarithm of the relative energy impressed.

While the decibel is commonly used in America, some of the European countries employ the *neper*, equal to the natural logarithm (base ϵ) of the ratio of two voltages or currents. If the power ratio is the square of the voltage or current ratio, the nepers $n = \frac{1}{2} \log_\epsilon (P_1/P_2)$. One neper is equal to 8.686 db. This unit has a natural significance in connection with the mathematical treatment of transmission problems. From a practical standpoint, the decibel has somewhat greater usefulness.

It cannot be too strongly emphasized that the decibel measurement is, of itself, merely a *power ratio*. It implies nothing as to the absolute amount of power, voltage, or current that may exist unless this is definitely indicated with the use of the term.

A *transmission-measuring set* is often used, and directly calibrated, by assuming that at the input end of the circuit or equipment concerned, a steady source of 1-mw a.c. will be applied. Such devices are employed to a considerable extent in the telephone plant to check the attenuation of circuits, often at 1,000 cps. A transmission-measuring set is essentially an amplifier-rectifier, connected to a d-c milliammeter, which is correct-reading when connected to circuits of a standardized impedance, commonly 600 ohms, for trunk circuits. With other impedances, corrections must be made. As noted, the transmission-measuring set does not indicate the absolute value of the speech power that may exist in the circuit when in use. However, its reading on steady currents is, in fact, decibels above or below 1 mw, generally abbreviated *dbm*.

Another instrument, the volume indicator, or VU meter, described in Chaps. 13 and 21, is employed where a rough indication of the absolute value of the speech or music power or volume in the circuit may be desired. This consists of a meter of standardized dynamic characteristics whose fluctuations follow, roughly, the major fluctuations of the speech energy in the circuit. Its constants were originally determined experimentally to reflect the instantaneous speech-energy characteristics which are of significance in the case of some types of equipment, such as amplifiers, subject to peak overloading. It is necessary to follow a prescribed technique for reading a VU meter; the maximum excursions of the needle of the instrument are noted within a given period of time. With experience, the reading can be checked, to a fair degree, by different observers.

32. Phase and Delay Considerations. It was assumed for many years, following the early experimental work of Helmholtz, that, while the ear is fairly critical of amplitude-frequency distortion, it does not appreciate phase or delay differences between the different frequency components. In more recent years more careful experiments have revealed that this is not strictly true even for ordinary speech, and particularly is not so in the case of sounds from musical instruments. In the latter case, for highest-fidelity rendition, close phase control, as well as very-wide-band transmission, is desirable—over a range from as low as 20 cps to frequencies well above 10,000 cps, depending on the instrument.

Television transmission is also very sensitive to phase differences throughout the several-megacycle-wide frequency band involved. Telephone or data-transmission systems involving frequency modulation or pulse transmission—particularly multichannel systems—are unusually sensitive to phase distortion. Instruments are available for measuring phase delay.

Phase distortion occurs to only a slight extent in simple uniform wire-transmission circuits, either cable or open-wire, where there is no abrupt transition in attenuation as the frequency is raised. However, in *loaded-line circuits, i.e.*, circuits in which inductance has been added at intervals in series with the wires in order to reduce the

attenuation, resulting in a comparatively sharp cutoff in the attenuation-frequency characteristic, there is considerable phase change in the region approaching the cutoff frequency. Similarly, in types of equipment where the band of frequencies involved is restricted by network or filter circuits, there is also likely to be considerable phase change in the neighborhood of the transmission characteristic where the losses increase rapidly.

The effects of such phase changes can be reduced by adding to the circuit special correcting networks called *phase equalizers*. In some cases, it may be feasible to restrict the employed range of frequencies to a band which avoids the frequency range where the phase change is most severe.

The situation seldom, if ever, arises as a practical factor for ordinary speech and is scarcely noticeable except on the longest circuits. Even there, it impairs the naturalness only slightly while not seriously affecting the intelligibility.

Absolute time delay in transmission is occasionally a factor. On open-wire-line circuits the velocity of transmission approaches that of light. Nonloaded cable circuits, depending on the gage, have a velocity only a fraction of this in the voice range but approaching 150,000 miles per sec at high frequencies. The application of loading to circuits may slow down the velocity to only one-tenth this figure or less. Coaxial circuits have a high velocity of transmission, and, of course, the radio medium is high velocity.

However, delay frequently occurs in substantial magnitude in the terminal equipment of radio or carrier systems when the currents pass through networks or filters. Frequently such delay is greater than that which exists in the medium itself.

Delay, if permitted to exceed $\frac{1}{10}$ or $\frac{2}{10}$ sec, may be annoying to a user because, when he speaks into the transmitter, he receives side tone not only directly from within the telephone set itself or through the air but, also, to some extent, from reflections along the line circuit and, in particular, from the far terminal of the line which may be several hundreds or thousands of miles distant. The latter side tone, while not necessarily approaching the volume of the speech received on the circuit, may still be very annoying to the talker if it is delayed appreciably beyond the speech itself. In effect, it becomes an *echo*.

In the case of circuits exceeding 1,500 miles or so, arrangements are frequently made to introduce *echo suppressors*. These are voice-operated devices which, when speech passes through them in one direction, interrupt the transmission path in the other direction. This is feasible since the majority of longer-distance circuits are so-called *four-wire* two-path circuits, or perhaps *equivalent four-wire* where different frequencies are employed for transmission in each direction in carrier or radio systems.

If the delay in transmission from end to end of a long circuit is extremely great, involving a substantial fraction of a second, this may bring about an undesirable situation because it takes so long for the person at the receiving end to get the message and, if he wishes, to interrupt or reply to the first speaker. This can happen, particularly in cases involving a combination of unusually long land and overseas transmission paths. There is not much that can be done to alleviate this situation except to keep out of the longer circuits those elements which reduce speed, such as loading. As a matter of fact, loading is currently being installed chiefly only on intra-area exchange trunks. Some medium-distance loaded intercity circuits, installed many years ago, are being rapidly unloaded for the application of carrier systems.

33. Noise. It is evident that, while, theoretically, circuits might be permitted to extend to great distances with the expectation that the attenuation could be overcome by applying an amplifier at the end to offset it, if there are sources of unwanted current or noise somewhere along the circuit, there is a definite limit to the amount of amplification which can be employed. Otherwise the noise current may compare with, or even exceed, the wanted speech currents.

Practical experience and tests indicate that a person is disturbed by some types of noise when it is stronger than 30 db below the average energy of the speech. Actually, of course, noise greater than this can be tolerated in speech circuits, at least for short

intervals. By concentration, not too much intelligibility is lost when there is a signal-to-noise ratio as low as 10 db. Such conditions are, however, not proper standards for satisfactory day-by-day telephone service. Where telephone circuits are used for some forms of data transmission, even more severe noise limits must be met.

The character of the noise plays a part in determining the disturbing effect. In general, steady regular wave-form disturbances are less annoying than erratic or sharp high-peak-value transients. Noise which sounds like speech, even though not intelligible, is sometimes very disturbing.

Noise can be controlled in various ways—sometimes by suppressing the source of the disturbance. For example, noise which results from the induction from power lines into telephone circuits is generally not the result of the 60-cycle power field but of higher harmonics which are inadvertently produced in some generators and power-converting devices, such as rectifiers. These harmonics may involve frequencies throughout the whole voice range and, while not representing a large percentage of the power transmitted, are frequently of sufficient strength to induce substantial currents in telephone circuits, particularly open-wire circuits.

It is possible, by improving the design of the power generators or converting devices, in some cases applying chokes or filters in the power circuits, to effect considerable improvement in particular situations. By applying transpositions in the power circuits as well as by means of transpositions in the telephone-wire circuits, a substantial reduction in induced noise can also be effected. Carrier systems, as in radio, are sometimes subject to interference from static, also from radio stations having overlapping frequency ranges.

Cable circuits, by virtue of the close spacing and continuous twisting of the conductors forming a pair and also because of the metal sheath, are much less sensitive to picking up noise from external fields, such as power and other sources.

34. Balance. Most metallic circuits in good repair are inherently fairly well balanced to ground by virtue of their constructional symmetry, but if they are connected to equipment which is unsymmetrical to ground and which has any appreciable degree of *resistance* or *capacitance unbalance*, this will tend to convert cross talk or noise currents which may be picked up in the longitudinal circuit of the pair and transfer it into the metallic circuit. It is important therefore that equipment intended to be connected to balanced line circuits be carefully designed.

A common method of expressing unbalance in circuits and equipment is to measure the microamperes induced in the metallic circuit per volt applied to the longitudinal line circuit. Well-constructed and maintained open-wire or cable pairs may, of themselves, be unbalanced to the extent of 0.5 to 3.0 μa per volt when terminated in essentially perfectly balanced receiving equipment. It is desirable to have the equipment balance better than this figure. The over-all unbalance of the circuit and equipment should be a minimum in order to minimize the noise received, particularly where the noise pickup from external sources in the longitudinal circuit is substantial, as it may well be, even in shielded-cable circuits.

35. Resistance Noise. Actually, if circuits could be perfectly shielded, electrostatically and electromagnetically, from external noise of all sources, there would still remain inherent in the circuit itself a noise source which is the result of the continuous random movement of the electrons in the conductors. This so-called *resistance noise* or thermal noise is a function of the temperature of the conductor and the band width of the circuit. Its frequency distribution is essentially uniform. It is seldom a practical factor in the design and layout of most telephone circuits since it is much lower in power than the noise which usually appears from external sources or is picked up incidentally in the equipment.

The resistance noise which appears in a telephone circuit at 70°F is of the order of 140 db below 1 mw. However, there are a few practical cases where noise from external sources is low, such as in a long overseas submarine cable, where resistance noise may be a controlling factor.

After all ordinary measures are taken to reduce unwanted currents or noise which

enters a telephone circuit, the only remedy possible is to ensure that the speech level does not sink so low in traversing a circuit that it approaches the level of the noise currents. This can be accomplished by applying amplifiers (*repeaters*) to raise the level of the speech currents at frequent intervals along the circuit. In laying out a circuit and spacing the repeaters, consideration must be given to the number which will appear in the over-all circuit, and whether the particular circuit involved is only one of several which may be connected in tandem. Even though a certain signal-to-noise ratio may be permissible for a single link circuit, if several may be connected, each must be designed to have a somewhat higher signal-to-noise ratio than desired in the over-all multilink circuit.

Noise is commonly measured by connecting to the circuit a so-called *noise-measuring set*. This has some elements in common with a VU meter, except that it is usually more sensitive and its frequency-transmission characteristics are adjustable to simulate the telephone receiver plus the approximate human-ear sensitivity to disturbances. VU meters have sometimes been used with the necessary extra amplification in the absence of a regular noise meter. Noise measurements are commonly expressed in decibels above a base, which is approximately at 85 db below 1 mw.

36. Impedance. As noted previously, the impedance of circuits and equipment which make up long telephone circuits must be carefully considered. Failure to match impedances, where two circuits or equipment units join, may result in increased losses and/or transmission-frequency distortion. For example, the characteristic impedance of an open-wire circuit, having 12-in. spaced conductors, is of the order of 600 ohms throughout both the voice and carrier frequency range. A nonloaded cable pair has an impedance of the order of 100 ohms in the carrier range. If two circuits of these respective types and of substantial lengths are directly connected together, the over-all loss will include not only the attenuation loss of the individual circuits concerned but a reflection loss of about 3 db, which may be serious.

The remedy for impedance problems is either to design the circuits and equipment so that they conform to uniform impedance values, 600 ohms being an accepted standard for most regular telephone plants, or, if junctions are to be made between circuits having different impedance, to include transformers, generally called *repeating coils*, having proper turn ratios, at the junctions in order to minimize reflection effects.

Sometimes impedance-transforming networks or autotransformers can be applied, particularly where it is desired to preserve the d-c continuity of the circuit. The treatment is not always simple because the impedance of line circuits and devices is not constant with frequency and includes the reactive as well as resistive components.

37. Transmission Standards. With telephone sets of the general type described in Sec. 2, it has been established, by measurements and tests, that the requirements for reasonably satisfactory transmission are satisfied if the over-all attenuation between two users is not greater than about 25 db. It is assumed in this connection that the transmission characteristics of the over-all circuit provide a band width from roughly 200 to over 3,000 cps, at which points the attenuation is no greater than 10 db above the mid-band attenuation, and that the variations throughout the band do not exceed a few decibels. It is assumed, also, that the circuit noise entering the receiving telephone set is at least of the order of 40 to 50 db below the speech power leaving the transmitting telephone set, with the cross talk at least 60 db below.

The transmission designer will need to consider many factors in specifying the design objectives for the different trunk and loop circuits involved, obviously with a detailed knowledge of the economics of the situation. In a nationwide system, in addition to two loops at the terminals of the connection, there may be other trunks between the end offices, and perhaps also between *toll centers*, *primary centers*, *sectional centers*, and *regional centers*, these being the successive steps in an echelon of switching organization. In fact, a complete intercity connection between subscribers may have as many as eight or nine links. With automatic switching, there is no serious barrier from the standpoint of speed of service in having many links, and considerable advantage in flexibility. Manual switching previously placed a greater premium on direct circuits.

The total permissible loss for each link is not necessarily a proportionate fraction of the 25 db suggested as an over-all design objective nor is 25 db necessarily a limit for all the future because, with time, improvements in equipment and techniques will probably permit continuing the trend in the direction of still lower-loss transmission standards.

In general, it costs very little more to provide close-to-zero-loss long-distance trunks, where amplifiers are needed in the circuit in any case. It is, of course, also desirable to engineer the circuits in such fashion that different connections are reasonably alike in volume irrespective of the distance involved.

The use of volume indicators, or VU meters, has not, in general, been very extensive in telephone-system practice except in the maintenance and setting up of special circuits, such as broadcasting, where the order of magnitude of the power cannot always be predetermined as well as for regular telephone use.

However, they are being tried out for periodic checkups of over-all system transmission performance by connecting them across a point in the circuit at the office end of a user's loop and, over a period of time, noting the VU readings when speech is being received from a distant user. A better alternative might be to connect them across the user's set itself, but this is not very practical.

Such readings at the central office are significant as to the over-all transmission a user is receiving. They include the effect of the complete transmission-line circuit from the distant user and, in addition, of course, involve the loudness with which the distant user is speaking and how he holds the telephone. Some skill is needed in interpreting the results of such a volume-indicator survey and considerable data are necessary before judging as to what, if anything, may be wrong with the telephone circuits or equipment.

Based on subjective studies, it appears that a received volume above −34 VU or so would be generally rated by the receiving party as good, between −34 and −40 VU as fair, and below −40 VU as poor. These figures assume a receiving loop with attenuation of about 5 db and a 300-type telephone set somewhat older in design than the 500 set described in Sec. 2. Of course, as noted previously, a low measurement in any particular case may be due either to faulty circuits or equally as well to an habitually weak talker or one having other imperfect telephone habits.

WIRE CIRCUITS

38. Types of Wire Circuits. The first circuits for telephoning any distance followed earlier telegraph practice and consisted of a single bare wire supported by insulators on poles, with a ground connection at each end. It was soon found that, when two such *ground-return* circuits were operated on the same pole line for a substantial distance, induction between them caused considerable speech on one circuit to be overheard on the other. A great reduction in this *cross talk* resulted from the general adoption of a *two-wire circuit, i.e.*, with metallic rather than a ground return.

Circuits are subject to interference not only from other telephone circuits but from nearby power lines as well as static and lightning impulses. The two-wire circuit is, of course, not, of itself, adequate to control the noise situation in all cases, as discussed in Sec. 33. Unwanted currents may, of course, also arise inadvertently in the equipment, from power sources in amplifiers and the like.

Wire circuits employed for telephony range from the simple twisted pair through various types of multipair cable circuits and open-wire lines to the more complex coaxial conductor. The variations in size and performance are numerous.

Simple insulated pairs may be used for interior wiring to telephone sets within a building. In a typical case use is made of one or two pairs of 20-gage copper-steel conductors, with plastic insulation, and a jacket colored to harmonize with room trim and thus remain inconspicuous where it is not possible to conceal the wire. In large-scale installations, cables of many pairs, usually 24-gage, may be run within the walls, in ducts or runways.

A much more substantial pair construction is used to provide the *drop wire* from a

telephone pole to a user's home. Since spans of 200 ft or more are sometimes necessary, the tensile strength of such wire is important. Eighteen (18) gage is usually employed, the wire being of a high-strength alloy or possibly copper-clad steel. Such wire has a strong insulation, such as buna rubber, and is jacketed with tough abrasion-resistant neoprene or other plastic to afford protection when it comes in contact with tree branches.

The transmission characteristics of interior wire or drop wire are not a prime consideration since the lengths involved are short.

39. Loop Circuits. For transmission over the loop circuits from users to central office, a cable, made up of many pairs of wires under a moistureproof sheath, is most commonly employed. This cable may be laid underground, in ducts in cities, or perhaps supported aerially from poles. Where single cables are involved, there is an increasing use of direct burial underground without ducts.

Depending on the demands of service and the distances involved, such cables may range from a few pairs upward to several thousand. The gages range from No. 19 to No. 26 B. and S. The increasing cost of copper has encouraged the application of aluminum wire in some instances.

Older practice has been to insulate the pairs making up the cable with spiraled paper or paper pulp. Currently, plastic material, such as *polyethylene*, is being used for insulation. Also, older construction generally employed thin lead sheaths over the bundle of conductors. Current practice is to use a plastic, such as polyethylene or polyvinyl chloride, sheath with an aluminum or a steel and aluminum sheath underneath.

Sheath damage, with consequent leakage of moisture into the cable structure, presents a serious problem, particularly in the case of paper-insulated conductors, where the moisture penetration may affect the transmission on many pairs. This has led to fairly extensive pressurizing of the cables so that a leak of substantial size can be detected rapidly and moisture can be prevented from entering the cable as long as the pressure is sustained.

The pressure on the interior of the cable is applied, usually by means of nitrogen gas in cylinders or air from compressing and drying equipment, at about 10 psi. Facilities for measuring the pressure at various points along the cable make it possible, by comparing measurements, to locate a leak to a fair degree of accuracy.

40. Open-wire Line. Where not too many circuits are involved, open-wire lines are still employed to some extent in loop circuits. This is the case in some rural areas. Open-wire lines may have *crossarms* supporting from 2 to 16 glass insulators. There may be from one to four crossarms, sometimes more, totaling 20 or more pairs of wires.

The two wires constituting a pair are commonly spaced 10 or 12 in. apart, with the same spacing between pairs. On some lines, where it is desired to use carrier systems with frequencies above the voice range, it has been found useful to employ pair spacings as close as 8 in. to minimize cross talk. Experiments are also currently being made with 6-in.-spaced pairs, where one or both wires have a thin cover of plastic insulation to minimize the chance of the conductors touching when swinging in the wind.

The sizes of open-wire conductors range from 80 to 165 mils (diameter). In the case of short lines, where the attenuation may not be so critical, galvanized-steel wire is sometimes employed. This permits greater pole spacings, up to 600 ft, because of the additional strength. In addition, there is the lower cost of the conductor itself. Copper-clad steel has also been employed. Galvanized-steel wire and, to a lesser extent, copper steel have the disadvantage of having higher resistance and, consequently, greater attenuation than copper of approximately the same size at high frequencies; however, copper-clad steel is essentially as good as all-copper wire.

Transposition. Cross talk is a factor whenever circuits exist in close proximity in either cable or open-wire construction. In the case of open-wire lines, cross talk is minimized by interchanging the positions of the wires of a pair at intervals to form a

so-called *transposition point.* Where there are a number of pairs on an open-wire line, the location of these transposition points differs for the different pairs and must form an orderly pattern. The transpositions for the different pairs are generally chosen from fundamental types shown in Fig. 6 of Chap. 27. In the case of pairs used for high frequencies, the locations of the transpositions must be quite precise.

In the case of pairs of wires in cables, the inductive effect between pairs is minimized by continuously twisting the different pairs. It is arranged, in laying up the cable, that those pairs which are in closest proximity have different rates of twist. A cable pair may have any one of several different rates of twist, depending on the location of the pair in the cross section of the cable.

41. Trunk Circuits. Intracity trunk circuits are almost exclusively of cable construction, either underground or overhead. They are frequently loaded at intervals of from 3,000 to 6,000 ft, as described later. Intercity construction may also have somewhat similar characteristics except that the gage employed, mostly No. 19 gage, is larger than the pairs generally employed in loop circuits.

In intercity cables, the pairs are sometimes used as voice-frequency *four-wire circuits, i.e.*, for one-directional transmission. All the pairs for a given direction of transmission are often grouped and separated from those of the opposite directional transmission. In a few cases these groups of conductors have been shielded with a covering of thin foil to minimize further the cross talk between the opposite directional groups, particularly when the pairs carry high frequencies. In most cases of long carrier systems having the same frequencies in opposite directions, separate cables are used.

Cross-talk problems are more severe between opposite directional circuits than where the circuits concerned transmit in the same direction. This is because the difference in levels of the speech currents near the input or output of repeaters in the opposite directional pairs may be substantial. In general, intercity cables are more carefully controlled in uniformity of construction, particularly to minimize cross talk, than exchange-area cables.

Where *phantom circuits* are involved, the pairs are first grouped, two pairs together, termed a *quad*, and these are given a separate spiraling in addition to the spiraling of the individual pairs in order to reduce quad-to-quad cross talk as well as quad-to-side-circuit cross talk. There is also a *star-quad* nonphantom construction, not so common in America but more common in Europe, in which the two pairs making up the quad have their two respective conductors arranged noninductively at the diagonal corners of a square. Thus the side circuits are not individually spiraled but the star or *spiral-four* quad is spiraled as a unit. Such a quad saves some space in the cable.

Quite frequently long-distance intercity cables and distribution cables are laid directly underground without being drawn into underground ducts. Armor wires or tapes for physical protection and perhaps some extra defense against lightning are added over the cable. Some of it may be laid by tractor-drawn plow-type machinery which does not require that a trench be opened up and backfilled.

For some intercity lines, there is still a fair use of open-wire construction, particularly where not too many circuits are required. The cost per circuit mile may be lower, among other things, because the attenuation is lower and they require fewer repeaters than cable circuits. These open-wire lines are not dissimilar to those used in loop circuits but usually are more rugged, having heavier poles, shorter spans, 150 ft or less, and larger wire sizes, in some cases 165 mils. Such well-constructed open-wire lines have a good degree of reliability, although in areas where there is much sleet, they are sometimes vulnerable.

42. Coaxial Cable. The *coaxial* conductor is a preferred form of construction where the transmission of exceptionally high frequencies is involved. It consists essentially of a flexible cylinder surrounding an interior solid or stranded conductor. From an attenuation standpoint, it is good for high frequencies for, in the case of the outside conductor, the high-frequency resistance is especially low because the *skin effect* is minimized. Furthermore, a coaxial structure tends to be self-shielding at the high frequencies and is not vulnerable to external fields. If the insulation is largely air, as

is the case for the coaxial circuits used in the telephone plant, the dielectric losses can be kept low and this again promotes its effectiveness for frequencies in the megacycle range. In this case the central conductor is supported by thin, circular-shaped spacers of polyethylene so that, effectively, the dielectric is about 95 per cent air.

A standard coaxial conductor, generally used for carrier and television transmission, has an internal diameter of the external pipe of 0.375 in. The inside conductor consists of a solid wire. The outside conductor is a long thin copper strip which has been folded in cylindrical shape, with a butt joint, the joined edges having small intermeshed teeth, and the whole bound together tightly by a serving of thin steel tape. Great precision is required in manufacture to maintain uniformity of transmission and impedance characteristics. Its flexibility permits it to be made up in cables which may contain several coaxials as well as numerous small-gage pairs, if desired. Eight coaxials, as well as some ordinary pairs, are often included in such a structure, as shown in Fig. 18.
FIG. 18. An assembly of eight coaxial cables.

Solid dielectric coaxial lines are often employed for short distances in connection with the wiring of high-frequency equipment. In general, their losses are too high to make them economical for the longer circuits except where great compressional resistance is required, as in a deep-sea cable.

43. Local Video Lines. Another form of special conductor has been employed, to some extent, in trunk circuits, around cities, for television transmission. This is a pair rather than a coaxial. A coaxial circuit, while well shielded at high frequencies, is not well shielded at very low frequencies. For the transmission of television programs on a noncarrier basis, where frequencies approaching zero are involved, a balanced pair can be made to be insensitive to low-frequency, as well as high-frequency, interference.

One form of this special high-frequency *video pair* consists of two No. 16 gage wires, each of which has a thin cover of gas-expanded polyethylene, and which are twisted together with two interstice fillers of expanded polyethylene over Fiberglas string. It is covered with a polyethylene wrap and a longitudinal copper tape shield.

It has an attenuation of something like twice that of standard 0.375-in. coaxial conductor. If used for ordinary television transmission for distances of greater than 4.5 miles, it must be equipped with repeaters at 2- to 3-mile intervals. Frequencies up to 10 Mc can, if necessary, be transmitted over such conductors.

44. Wire-transmission Characteristics. In a wire circuit of uniform construction, the attenuation in *decibels* per unit length can be computed from the formula

$$A = 6.141 \sqrt{\sqrt{(R^2 + \omega^2L^2)(G^2 + \omega^2C^2)} + RG - \omega^2LC}$$

where A = db per unit length
R = resistance per unit length
L = inductance per unit length
G = leakage per unit length
C = capacitance per unit length
ω = $2\pi \times$ the frequency in cps

Of course, the same unit length must be employed in the computation, and the units expressed consistently as, for example, ohms, henrys, mhos, and farads.

For very low frequencies, the computation poses little difficulty since the constants involved are essentially d-c values. However, as the frequency is raised, the so-called constants take on other values because of skin effect and other factors.

Skin effect and related phenomena result from the fact that the currents at higher frequencies tend to redistribute themselves throughout the cross sections of the conductors and travel a path of least impedance. Thus, in the case of a simple conductor
FIG. 19. Attenuation of 128-mil copper. Calculated for hard-drawn copper at 68°F with 53 pairs of insulators per mile.

of circular cross section relatively remote from the return circuit, the current will tend to avoid the center of the conductor and crowd the outside layers to a degree, depending on the frequency. In the case of very high frequencies, the current effectively travels only in a relatively thin surface layer. Where the conductors of a two-wire circuit are in relatively close proximity, as in a cable pair, this same tendency results in the currents' crowding the portions of the conductors which are closest to each other.

It is evident that this redistribution of the currents as the frequency is varied will not only determine the effective resistance of the conductor but will also affect the inductance and capacitance per unit length.

45. Line Leakage. Another difficulty in predicting the attenuation is the matter of the effective leakage. For higher frequencies, this not only is made up of the d-c

component but also includes effectively all dielectric losses in the circuit. For higher frequencies, with solid dielectrics, as in cables, these losses can be appreciable. Together with the resistance of the conductor, they may also vary with temperature and time and other external circumstances.

46. Environment Factors. Open-wire lines are unusually susceptive to variations with time. The chief offender is the variation of leakage with degree of moisture on the insulators. Not only may this leakage result from direct surface conduction over the insulator when coated by rain or fog, but the dielectric losses in the insulators may play an important part when the frequencies are high. An unusually serious condition exists when the insulators and wires are covered with ice in some form, with sleet or perhaps hoarfrost, a crystalline deposit which, in some special conditions of fog and temperature, may coat the wires and insulators to a depth of several inches. These conditions, with ice having an extremely high dielectric constant, may completely upset the attenuation, as will be appreciated from some of the data included in curves given in Figs. 19 to 23.

Fig. 20. Attenuation due to ice, snow, and frost on open-wire pairs of hard-drawn copper.

In general, the characteristic impedance of the wire circuit is less affected by the variations in line constants with time and temperature.

Typical characteristic impedance curves are given in Fig. 24 for 12-in. spaced open-wire conductors for frequencies from 0 to 150 kc, also in Fig. 25 for typical cable circuits from 0 to 150 kc for No. 19 gage conductors.

47. Loading. It is generally possible, with most common wire circuits, to reduce the attenuation by increasing the inductance per unit length. This is termed *loading.* It can be carried out by uniformly surrounding the conductor with a thin layer of magnetic material of high permeability, which is known as *continuous loading.* This has been used, to some extent, in the construction of some long submarine-cable circuits for telegraphy as well as telephony.

However, loading is usually introduced in telephone circuits by connecting *loading coils* in series with the conductors at intervals. These consist of a magnetic core having two windings, through one of which passes one conductor and through the other the second conductor of the pair. The spacing of the loading coils must be a fraction of the wavelength involved for the highest frequency it is intended to transmit. Such *coil loading* has a *cutoff frequency* beyond which the attenuation rises to extremely high magnitudes. Within the transmission band the attenuation is usually of the order of one-third to one-half that of the corresponding nonloaded pair.

FIG. 21. Copper-clad-steel pairs of 128-mil wire, 68°F and 53 pairs of insulators per mile.
FIG. 22. Typical attenuation of 19-gage cable pairs.

The addition of loading raises the characteristic impedance of the circuit, and this tends to exaggerate the leakage losses. Loading is therefore not generally regarded as a good expedient where it is expected to use the highest frequencies on a line, where leakage losses may predominate.

In the earlier days of telephony before the advent of vacuum-tube amplifiers and the use of high frequencies to transmit several channels over the same conductors,

loading was common on the longer wire circuits, both open-wire and cable. These practices have been largely discontinued, and, indeed, many circuits, originally loaded, have been unloaded.

Loading is currently being installed in the telephone plant mostly on the relatively short intracity cable circuits where, alone or in combination with repeaters, it is the most economical method for obtaining satisfactory overall losses. Carrier techniques are becoming cheaper, and with the prospect of a more extensive application of transistors, it seems not unlikely that loaded voice usage may be limited to circuits up to 8 or 10 miles in length in the not too distant future.

48. Phantom Circuits. Two sets of conductors, each individually used for two-wire or four-wire transmission, can be connected, by the use of *repeating coils* or phantom coils, to provide a third so-called phantom circuit, as shown in Fig. 26. The currents of the two side circuits flow in opposite directions for the pair, while the poling of the windings of the repeating coils is such that the phantom-circuit currents flow in the one direction over both sides of one pair and in the opposite direction over both sides of the other pair. Therefore, there is little or no cross talk between the phantom circuit and either of the two side circuits if the repeating coils are accurately wound and tapped and the line is well balanced.

Fig. 23. Attenuation of high-frequency conductors.

Fig. 24. Dry-weather impedance, 12-in. copper pairs, 68°F and 53 pairs of insulators per mile.

A 50 per cent increase in the circuits provided by a given number of conductors is thus obtained for the cost of the repeating coils, which must be installed at each terminal, with some complication in the arrangements needed to minimize the cross talk between not only the phantom and side circuits of a quad, but also the phantoms and side circuits of other quads in the same structure.

The attenuation of such a phantom circuit, because of the increased amount of

copper involved, is somewhat less than that of the side-circuit pairs. Its characteristic impedance is also slightly lower. Phantom circuits have been used, to a fair extent, in the past in the trunks of the telephone system. However, their use is uneconomical in most cases now.
Fig. 25. Typical values of characteristic impedance, 19-gage pairs, 55°F.

49. Composite Sets. When a wire circuit is used for telephony, it commonly requires the transmission of frequencies no lower than about 200 cycles. This leaves a range from this frequency down to zero available for other purposes, such as d-c signaling or telegraphy. A separation between the frequency ranges is made by a network of inductances and capacitances, known as a *composite set.*

A simple composite-set circuit is shown in Fig. 27. The inductances are of the order of 3 henrys and the capacitances 2 μf. The ground connection makes it possible to employ the two sides of the pair in ground-return circuits if it is desired to take advantage of the two separate paths provided thereby. Such composite-set arrangements are employed chiefly in trunk circuits.

REPEATERS

Repeaters are commonly installed at intervals in either wire or radio systems. The output of a repeater should, in general, be a faithful reproduction of what enters the repeater, except that the magnitude is stepped up, depending on circumstances, from a few decibels up to as much as 100. This is referred to as the *gain* of the repeater.

50. Four-wire Repeater. The simplest telephone repeater consists of two separate amplifiers connected in the two sides of a four-wire circuit to amplify in opposite directions, as in Fig. 28. At the input of the amplifiers, such a *four-wire repeater* may include transmission *equalizers* which provide amplitude-frequency distortion opposite to that which occurs over the line circuit which the telephone currents have traversed. The equalizer generally offers relatively high loss for the lower frequencies and low loss for the higher frequencies. The net effect is to ensure that the frequency-amplitude distribution of the speech power is

Fig. 26. Arrangement of phantom circuit.

essentially the same at the output of the repeater as it was at the sending end of the circuit.

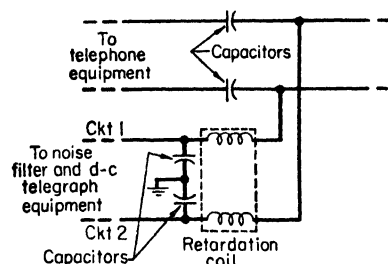
51. Two-wire Repeater. A more complicated situation arises in the case of a two-wire circuit used for speech in both directions. Here, if two amplifiers were directly connected to the line circuit in each direction to form a repeater, the gain of the amplifiers would considerably exceed the losses in the loop circuit thus established and the system


Fig. 27. Composite set circuit.
Fig. 28. Four-wire repeater.

would *sing*. This led, at an early date, to the adoption of the two-wire two-directional (22-type) repeater.

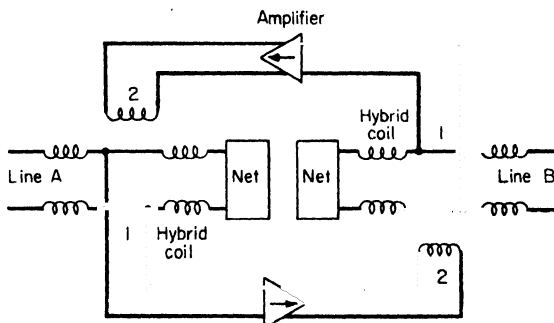
Here, instead of connecting the respective input of one amplifier and output of the other amplifier directly to a line circuit, there is introduced a balancing coil or so-called *hybrid coil*, as shown in Fig. 29. The output of one amplifier is connected to and passes through symmetrical but opposite poled windings on the coil, one path leading to the line circuit and another to a line *balancing network* whose impedance simulates that of the line. The input to the other directional amplifier is connected to another winding on the same core whose impedance is arranged to match the input of the amplifier. If there is a good impedance match between the line and network circuits, there will be a relatively high-loss feedback path around the two amplifiers. This permits substantial gain to be provided for each direction of transmission without singing.


Fig. 29. 22-type repeater.

In a practical case, of course, the balancing network does not provide a perfect simulation of the line impedance, particularly if the line is short electrically. The 22-type repeater gains in each direction are usually limited to something of the order of 20 db, often less than this when there are many repeaters in tandem on the circuit.

Fig. 30. 21-type repeater.

52. 21-type Repeater. A circuit where the conductors are the same in each direction from the repeater point lends itself to the operation of a so-called 21-*type repeater* in which the two directions of transmission pass through one amplifier circuit, as shown in Fig. 30. Such 21-type repeaters are not common and are limited to occasional use where only one repeating point is necessary. The ability to balance each side of the circuit independ-

ently usually makes it possible to obtain higher gains by the use of 22-type repeaters than with 21-type repeaters.
In the case of either the 22-type or 21-type repeater, equalizers may also be needed in order to control the transmission-frequency characteristics of the over-all circuit as noted previously.

53. Negative-impedance Repeater. A special type of two-wire repeater, employing only a single amplifier, has also come into extensive use, particularly for the shorter circuits, in recent years. This is known as the *negative-impedance repeater*. A schematic circuit of a *series* negative-impedance repeater is shown in Fig. 31. Some relationship to the 21-type repeater is evident, and it will be noted that the metallic circuit through the repeater is continuous, which is a matter of some importance where it is used in connection with d-c supervisory or signaling functions. The amplifier, often termed a *converter*, which supplies the negative-impedance function, is actually a controlled-feedback circuit, the associated network being so adjusted as to supply necessary frequency-phase control in the feedback circuit in relation to the line impedances and the desired degree of amplification. Various specific amplifier circuits are possible, generally of the push-pull type.
FIG. 31. E1 telephone repeater.
FIG. 32. Bridged-T repeater.

Shunt-connected negative-impedance repeaters are also possible, and in cases where high gains are desired, with minimum impedance irregularity, both series and shunt repeaters may be employed in combination. The schematic circuit of one such arrangement is shown in Fig. 32. It will be noted that, in effect, one converter-network circuit is in series with the line while the second one is in shunt with the line. In this case both networks must be properly adjusted to operate with particular line circuits.

Repeaters are also an essential element in the operation of carrier systems where many telephone channels are provided over the same set of conductors using a wide band of frequencies. Such repeaters must, of course, be designed to function satisfactorily over the wide band. In most cases, they require not only equalizers which ensure the desired amplitude-frequency characteristics but also some means for varying the amplification and degree of equalization with time to take care of the variations of the attenuation of the line circuits with temperature or weather. Phase equalization is sometimes necessary in such repeaters.

While, in the past, vacuum-tube amplifiers have generally been employed in repeat-

ers, it seems likely that there will be a gradual shift to the employment of transistor amplifiers, with a resultant reduction in size and power required, especially in intracity circuits where this is most important.

In a long radio circuit, particularly of the line-of-sight microwave variety, repeaters may be required at the limits of the line-of-sight distance, ranging from 25 miles upward, depending on terrain conditions. With scatter propagation, much greater distances are possible. Such repeaters can simply consist of r-f amplifiers whose terminals are connected to antennas from each direction. However, frequency translation is involved at such points.

54. Tandem Operation. The relation between attenuation, noise, and repeater spacing has already been noted, and frequently this is the only factor involved in the repeater layout of four-wire circuits.

Cross talk. However, cross talk is also a factor in some cases where it may be desired to employ substantial repeater gains. On wire circuits, where the two directions of transmission are in the same cable, cross talk could conceivably reach a point where the loss between the circuits connected to the output and the input of opposite directional repeaters would not be sufficient to prevent singing. This is not a very likely situation since cross talk between the high-level output of one circuit and the low-level input of other circuits would, no doubt, earlier have reached an undesirable point from the standpoint of privacy. The permissible gain at a repeater point must, however, be carefully considered in relation to the cross-talk situation which exists in the connecting cable or open-wire line.

In the case of repeaters on radio circuits, the cross talk between the input antenna in one direction and the corresponding output antenna in the other direction poses a somewhat similar problem. Since the desired gains in repeatered radio circuits are usually extremely high, the designer may be forced to use different opposite directional frequencies and thus supplement the directional characteristics of the antennas by frequency separation using filters. Frequencies of the two directions of transmission may, in this case, be interchanged within the repeater structure by frequency-translation equipment. Arrangements of this sort are employed in some types of carrier systems. Using different types of wave polarization also offers advantages in the case of two-directional microwave radio.

Impedance. In connection with *two-wire* repeaters, where the same frequencies are normally employed in opposite directions, the tandem operation of repeaters imposes special problems. All types of two-wire repeaters are dependent on the impedance characteristics of the wires to which they are connected. In a very long wire circuit, the impedance facing a repeater is essentially the characteristic impedance of the circuit and may not depend much on the condition of the circuit at the far end. If the line is of substantially uniform construction, it is possible to simulate the impedance of such a circuit in a balancing network quite accurately and, except for small changes with time and temperature or other weather-related circumstances, the balance provided is stable, and a fairly high repeater gain can be maintained. The gain will never, however, approach the loss of the over-all circuit to which the repeater is connected.

It may be desirable to introduce more repeaters in a long two-wire circuit at reasonable intervals. In this case, the connecting lines probably being electrically shorter, the impedance which faces the repeater will be determined by the characteristics of the line circuit plus the termination impedance, which could be a telephone set, another repeater, or other piece of equipment. If it is another repeater, the gain provided by its amplifiers may, in turn, help to reflect the impedance characteristics of a successive section of line plus some other termination or repeater equipment.

Gain. Thus, in general, the amount of gain permissible at each repeater point in a long two-wire circuit, having many repeaters, will be less than a single repeater established in a long circuit. Such tandem operation of repeaters can, however, by the necessary control of the impedance of terminal equipment and other repeater equipment, more nearly compensate for the attenuation of a long circuit than can a single

repeater installed at, say, its middle. The tandem operation of negative-impedance repeaters, particularly where both series and shunt devices are employed, can be quite effective in this connection.

However, under practical conditions, no two-wire repeatered circuit can quite approach the low over-all transmission loss of a four-wire repeater system, where the amplifiers and circuits are independent in each direction. The over-all performance of such a four-wire circuit from a transmission standpoint is generally determined by the balance provided at the hybrid coil, which is used to join the four-wire circuit to a two-wire circuit at the terminals.

CARRIER SYSTEMS

55. Carrier System Elements. The elementary carrier telephone system contains the same basic elements as a radio system. As shown in Fig. 33, the transmitters of several channels connect to a series of *modulators* fed by different high-frequency carrier-current sources, thence to selecting circuits or electrical *filters*, the outputs of which are joined to a common line circuit. At the receiving end similar selecting circuits or filters separate the modulated carrier currents of the different channels and lead to *demodulators*, by means of which the original voice currents are derived, thence to the corresponding telephone receivers of the different channels.
FIG. 33. Elementary one-way carrier system.

Two-way operation requires paths in the opposite directions. It is possible, theoretically, to provide two-way operation using the same carrier frequencies in opposite directions on the same set of conductors, with balancing arrangements similar to those of 22-type repeaters. However, this is not usually as practical as independent pairs of wires for transmission in opposite directions or *equivalent four-wire* operation using different frequencies over the same line circuit.

Modulation. The process of modulation may consist simply in *amplitude modulation, i.e.*, the variation of the amplitude of the carrier current in accordance with the variations of the speech wave. Actually, in this case, the resulting current, as brought out elsewhere in this handbook, consists of a mixture of the carrier current and currents of the two so-called *side bands*. The latter consist of the frequency of the carrier minus the modulating frequency of the speech at the instant, and the carrier frequency plus the modulating frequency of the speech at the instant. As has been noted, ordinary speech involves chiefly a band of about 3,000 cycles width, hence the term "side bands."

More refined modulation techniques are available by using combinations of circuitry and filters, the most common being the *single-side-band* (SSB) technique in which only one side band is transmitted, eliminating both the carrier and unnecessary complementary side band. All the intelligence is carried by the one side band, and this saves frequency space and power transmitted over the wire circuit.

Most types of carrier systems employ SSB because frequency space is expensive on wire circuits since the attenuation rises rapidly with frequency. The transmission problem is simplified thereby. However, where the distance of transmission is not too great and extreme simplicity of equipment is desired, double-side-band amplitude modulation is still employed.

Carrier systems occasionally employ other modulation techniques, such as *frequency modulation*, which requires greater frequency space than amplitude modulation. Forms of *pulse modulation*, which are, in general, even more lavish in the use of frequency space, have also been employed experimentally and, to a very limited extent, commercially.

Selectivity by simple tuned circuits has been employed to a slight extent but, more commonly, several-section *band filters* furnish the needed channel separation. For modulation and corresponding demodulation, the earlier systems employed vacuum tubes almost exclusively. Later systems employed copper-oxide diodes, while still more recently transistors or semiconductor diodes are being used in the newer carrier systems for the various functions of high-frequency generation and amplification, as well as modulation and demodulation.

56. Carrier Application. While carrier systems offer the chance to obtain more communication paths over a single set of conductors, their use must be carefully considered in each situation to determine whether it is less expensive than to provide additional separate conductors. This is because the cost of providing the equipment to carry on the necessary functions noted above tends to offset the savings in conductors.

In general, the use of carrier systems is profitable for the longer distances and has hitherto been almost entirely limited to trunk applications. However, the cost of the equipment has decreased and it seems likely that it will only be a matter of time before carrier systems are employed for distances as short as a very few miles, even for rural subscribers' lines. At the moment, the lower point of economical operation is of the order of 10 to 15 miles.

The earliest carrier systems were applied chiefly to open-wire lines where the high-frequency attenuation is comparatively low. They provided three or four additional channels with frequencies up to about 30 kc and with repeaters spaced at intervals from 100 to 150 miles. Later systems were designed for cable conductors using frequencies up to 60 kc and providing 12 channels with repeater spacings of about 17 miles. Then carrier systems using coaxial conductors came into being, providing up to 1,800 channels using frequencies up to 8 Mc and with repeater spacings of 4 to 8 miles. The latter systems can also be employed for wide-band transmission of television programs. By the end of 1956 something like 90 per cent of the circuits over 25 miles long were provided by carrier in the Bell system.

57. Power-line Carrier. Power-line carrier systems are extensively employed by power companies. In principle, they follow the general design of others using communication conductors, but the wire circuits in this case are the power conductors themselves. The connection to them is made, in general, through *coupling capacitors* capable of withstanding the high voltage of the power lines, at the same time passing the high frequencies of the carrier systems. Such carrier systems, in addition to their use for telephony, have also been employed by the power companies for various telemetering and power-control functions.

58. Carrier-system Choice. The choice of a carrier system for application between two points depends on a number of factors, the most important of which are naturally the distances concerned, the numbers of channels desired, and the available conductors. The possible optional or joint use of the system for other broad-band needs, such as television, may be involved in the situation.

The distance of transmission between carrier terminals depends on the gain and output capacity provided at the sending terminal, the line-noise conditions, and the receiving gain. Considerable distance can be spanned by the use of amplifiers at the sending end having sufficient gain and load capacity, but there is a practical limit in this connection. Usually it is less expensive to provide moderate power amplifiers at the terminals and employ repeaters at intervals along the route.

Noise into carrier systems, particularly open-wire, may include radio interference, sometimes from stations at some distance and where the frequency allocations of the carrier system and radio stations overlap.

The availability of power to activate the repeaters may, in some instances, be a

practical factor in the choice of a particular carrier system. Some systems, for example, the coaxial system, transmit power to several repeater points over the conductor which carries the speech. Thus they require a basic power supply only at infrequent intervals.

Another factor of considerable importance in laying out a carrier system is the matter of cross talk between systems operating on the same open-wire lead or on different conductors in the same cables. In general, this problem is minimized when systems of the same frequency allocation and power level are operated over the same line structure. Carrier systems tend to be incompatible if the frequency allocations are not the same or closely related. In particular, in the case where the same frequency is employed on nearby conductors but in opposite directions, the cross-talk problem is greatly magnified.

59. Frequency Allocations. In one type of system, often referred to as a *stackable* system, the channels may be added to a pair of wires one at a time. In this case the frequencies are assigned upward from the lowest usable frequency so that a single channel occupies opposite-directional adjacent frequency bands in the available spectrum. A second channel, perhaps installed at a later date, might then be piled on top of the first channel with its opposite-directional frequencies occupying channels 3 and 4. Other added channels would go to higher frequencies, up to a practical limit determined by the line characteristics and the capabilities of the terminal equipment. Such a frequency-allocation arrangement has the advantage of flexibility for growth, but it makes it difficult to apply repeaters at intervals where more than one channel is involved because of the relative complexity of the filter-separation equipment.

The preferred arrangement, where several channels are involved and it is necessary to employ repeaters, uses *grouped frequencies* in which the one-direction bands of several channels are grouped and the other direction of the respective channels occupies a frequency region adjacent to the first group. The two directions of all channels are therefore capable of being separated by a single set of *directional filters* and each passed through a single amplifier. Grouped-frequency systems and stacked-frequency systems are generally incompatible on the same lines because of cross-talk difficulties.

60. Signaling on Carrier Systems. All carrier systems must have provision for signaling and supervision over the channels. Sometimes the signaling arrangements are independent of the carrier system itself and simply consist of an application of signaling systems which are standard for other links in the toll plant. For example, one signaling arrangement applies to the voice band a modulated tone of 2,600 cps. This can be transmitted over a carrier telephone channel which may form part of a long telephone connection. Such a signaling system must, of course, be designed so that the tone is not present when speech is carried over the channel. Correspondingly, the signal-receiving equipment must not be susceptible to being triggered off when voice currents are applied to the sending end.

Another signaling system employs a frequency just outside the active telephone band at 3,700 cps, which is normally not employed for conversation. Such a signaling system is independent of the speech channel and, if necessary, functions with the signaling currents on the line at the same time as speech.

There are other signaling systems which operate by transmitting or interrupting the carrier current itself. It is important in selecting a carrier system to be sure that the signaling system provided is extremely reliable and that it will function under any condition of line attenuation or other influences which will still permit speech to be carried on. At the same time, it must not be triggered off by unwanted noises or transients that may, in some cases, be tolerable in the voice circuit.

61. Some Terminal Details. The channel-separating terminals of carrier systems are frequently also employed to provide multiplexing facilities over broad-band radio circuits. It is therefore convenient to consider in more detail one or two typical carrier-system terminals.

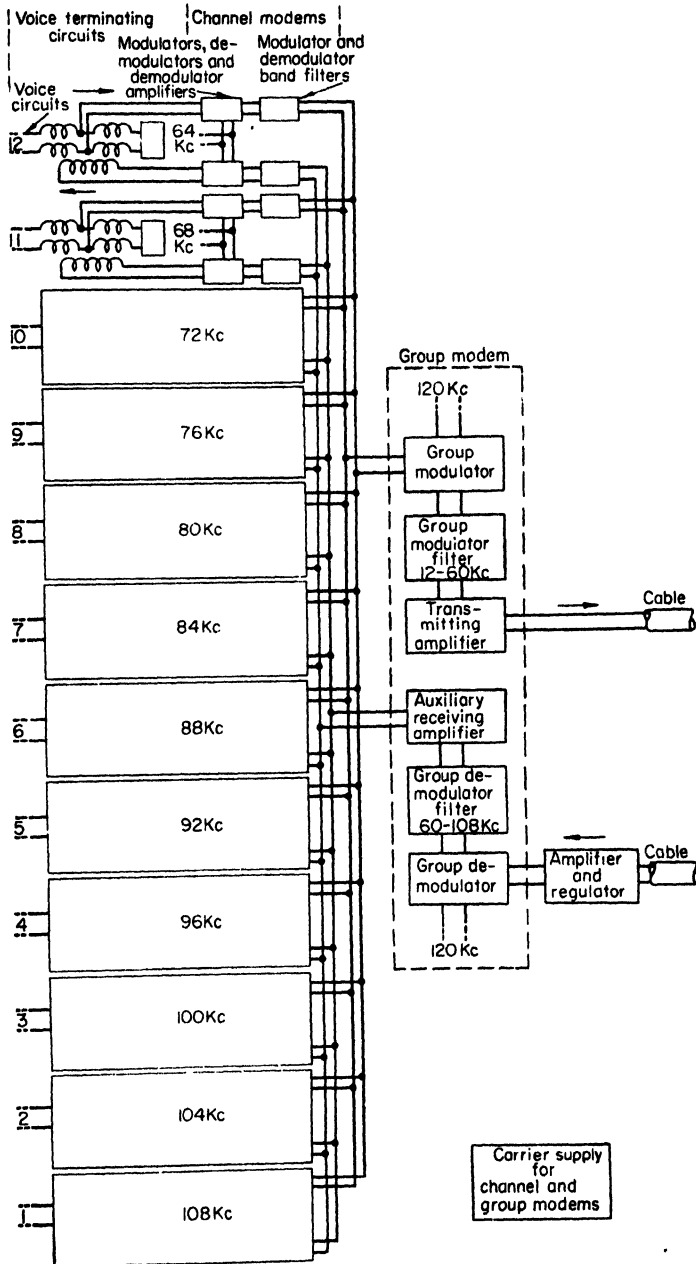
One typical system is the Western Electric *type K 12-channel* carrier system nor-


FIG. 34. Type K carrier-system terminal.

mally employed over 19-gage cable conductors, with repeaters spaced at intervals of 17 miles. This system uses vacuum tubes except for the modulators and demodulators, where copper-oxide rectifiers are employed in a balanced arrangement to suppress the carrier. A block diagram of a terminal of this system is shown in Fig. 34.

In this system there is an amplifier common to the 12 channels which is not unlike the amplifier used at repeater points. At the sending terminal of this system arrangements are also made to supply pilot-channel currents at the extremes of the frequency range which serve to regulate the transmission of a long system by changing the gain of the repeaters automatically as the line attenuation varies with temperature.

The channel filters select sharply at intervals of 4,000 cps, and the basic selection is in the frequency range from 60 to 120 kc, at which point very efficient filter operation is achieved using filters which contain quartz crystals as well as the usual inductance-capacitance elements. The frequencies are stepped down to the desired line-frequency range, from 12 to 60 kc, by the use of a second stage of modulation also employing copper-oxide rectifiers.

The K-system terminal is useful as an illustration because the 12-channel so-called *channel bank* is also employed as a building block in the arrangements to provide as many as 1,800 channels in one band for operation over wide-band coaxial systems or microwave radio systems.

Where the 12-channel banks are employed for this purpose, supplementary steps of modulation provide 60-channel *supergroups* which are, in turn, joined to give 600-channel *master groups*. In turn, three master groups can be joined to give 1,800 channels for a modern coaxial system.

This type K channel bank is intended for long-haul operation where many such channels may be operated in tandem for long connections. Thus each channel must have quite precise frequency-transmission characteristics in order that the over-all speech band may not suffer.

62. Frequency Stability Needed. Where large numbers of channels are involved, using very high frequencies, the precision of frequency of the carrier sources of the different channels must be high. This is achieved by deriving all the channel frequencies as well as intermediate modulation steps from a single precise high-stability oscillator.

If carrier frequencies in any system vary, not only will the speech be degraded over the channels because the side bands will not fit into the band filter characteristics, but also in an SSB system if the carrier supply to the demodulator differs from that supplied to the modulator of the corresponding channel, the voice will be displaced upward or downward in the frequency spectrum. This will make it sound unnatural because of the fundamental pitch change and the fact that the harmonics of the voice frequencies are also displaced relative to their natural position. A displacement of 20 cps is quite discernible for ordinary speech. For the transmission of high-grade music, the permissible variation is considerably less.

63. Type P System. Another carrier system of some interest is the Western Electric *type P system,* in which transistors have been exclusively employed for the first time to reduce size and cost and thereby provide a system capable of being justified for comparatively short distances, such as rural subscriber and combination open-wire and cable tributary trunk lines. This is a four-channel system using frequencies up to 100 kc.

A circuit diagram of one type P carrier-system terminal is shown in Fig. 35. It includes, in addition to the regular oscillator-modulator-demodulator functions, a *compandor* for each channel which compresses the volume range of the speech after it passes the modulator. At the corresponding receiving end there is an element using transistors which expands the volume to approximately the same volume range which existed at the sending end.

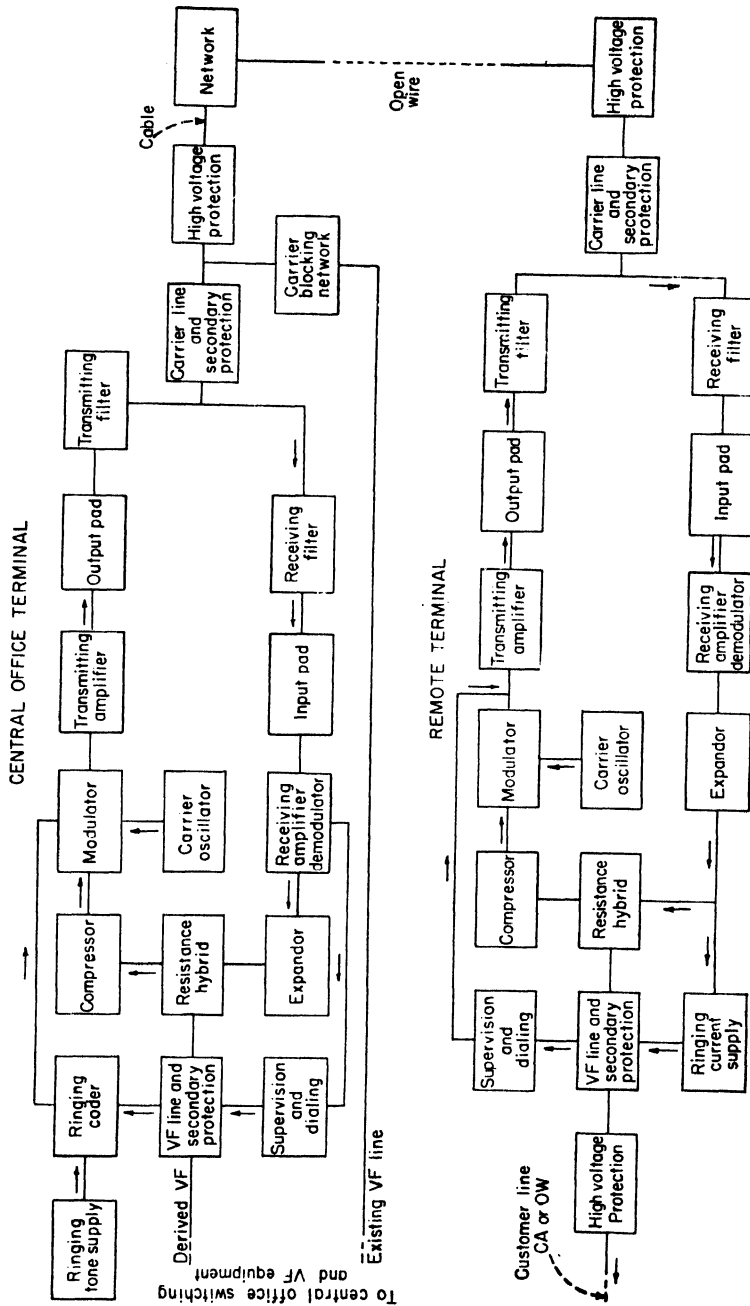
As a result of this compressor-expandor action, if there is noise on the line circuit, its effect will be reduced since the volumes of the speech-carrier currents on the line are sustained at a higher level above the noise currents than they would otherwise have


FIG. 35. Over-all block diagram of the P1 carrier system.

been. This advantage approaches 20 db and makes it possible to transmit over a longer distance than would otherwise have been the case for the same system without the compandor. Cross-talk problems are also simplified. The additional complexity of the equipment needed to include the compandor is, in most cases, worth the additional cost which it entails.

Compandors have also been used on other types of carrier systems; in fact, separate compandor units have been designed and standardized for application to other types of telephone circuits where special conditions make it necessary to minimize line noise.

64. Carrier Repeaters. Almost all type K 12-channel cable carrier systems require repeaters in the line circuit. The circuit diagram of a type K repeater is shown in Fig. 36. It is a feedback vacuum-tube device having circuits not unlike the other amplifiers basically, but provided with *pilot-channel* control circuits.

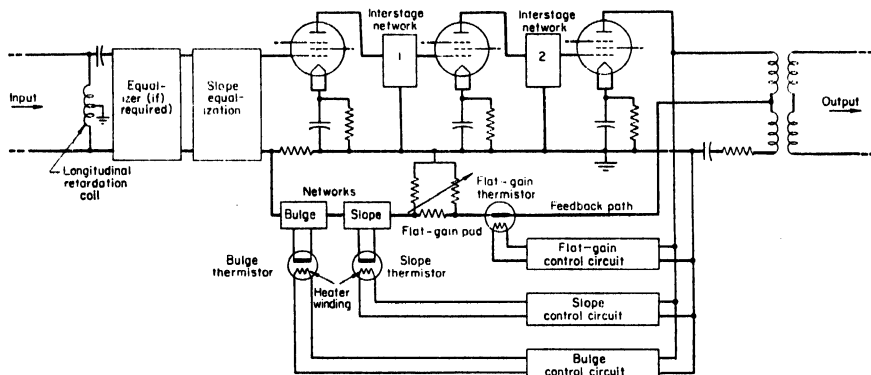
A pilot channel consists of a steady single-frequency current which is transmitted over the line circuit of a carrier system, the frequency being sandwiched between or at the extreme of the speech bands. Since the power of the SSB speech varies continuously, the pilot-channel current being transmitted over the same circuit provides a


FIG. 36. Type K carrier repeater.

better measure of transmission conditions, and it is affected in transmission like the speech bands. It can be used to adjust automatically the gain of the repeater to compensate for line variations with time, temperature, or other factors. The use of more than one pilot channel makes possible considerable refinement in the smoothness and accuracy of this adjustment over a very wide band.

In the *type K* repeater, the actual control is accomplished by incorporating in the feedback path of the repeater a network which has variable elements, so-called *thermistors*, whose resistances follow the variations since they receive their energy from the pilot currents selectively picked off the output of the repeater.

The design of such automatic control circuits involves some rather nice problems, not only of the static performance of the repeater to match the line variations with frequency and time, but also of the dynamic characteristics of the control circuit. This may be only one element in a complex feedback circuit involving as many as 50 or more other repeaters in tandem in a circuit several hundred miles in length.

As noted previously, the design of the amplifier for a carrier or radio repeater, which has several channels passing through the same set of vacuum tubes or transistors, imposes very severe requirements as to linearity. The intermodulation components must, in general, be kept at least 60 db below the speech channels so that excessive channel cross talk or noise may not result. In general, this calls for the use of a substantial amount of feedback.

The frequency allocation employed can also be a factor in the successful operation of repeaters since it is sometimes possible to arrange that the more serious intermodu-

lation components fall in the intervals between channels. Especially stringent requirements for linearity are imposed when many repeaters are operated in tandem over a long circuit and the resultant intermodulation components add. In designing or choosing a carrier system for long-distance operation, such factors must be carefully considered.

65. L3 Coaxial System. The repeaters used on the Western Electric Company L3 coaxial system deserve a special note. This system provides a total operational band of 8 Mc which can be split by the proper terminal equipment into as many as 2,000 telephone circuits, or used for one 4-Mc television band plus about 800 telephone circuits. It is operated over a standard 0.375-in. coaxial conductor, described previously under Wire Circuits.

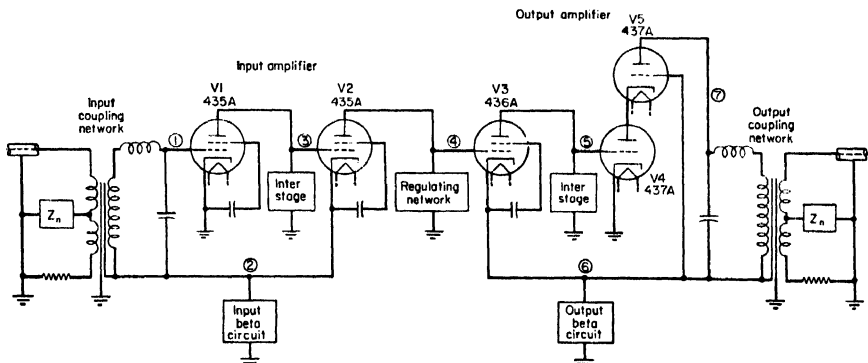
Because of the wide frequency band transmitted, repeaters are required every 4 miles. The system is designed for telephone transmission over circuits several thousand miles in length with hundreds of repeaters. This imposes extremely stringent requirements on the transmission design of the individual amplifiers from the standpoint of accuracy of transmission performance, stability with time, and the effectiveness of the multipilot system which is used to control the amplification to make


FIG. 37. L3 line-amplifier arrangement.

up for the variation in coaxial conductor attenuation with temperature. This has required, in the design of the system and provisions for its maintenance, much greater attention to detail than perhaps any other type of telephone transmission system ever created.

Because of the large number of repeaters, it has been found necessary to house them in nonattended underground vaults or, preferably, small huts. The repeaters are sealed in airtight containers to minimize the effect of varying moisture conditions. Power to the repeaters is supplied over the coaxial structure itself from a constant-current d-c source with primary power-supply points approximately 75 miles apart. As shown in Fig. 37, the circuit, in effect, consists of two two-stage amplifiers in tandem, each with independent feedback, and the tubes are a special high-transconductance, high-frequency type, designed for long life.

RADIO CIRCUITS

Where radio is used as a link in a telephone system, its transmission requirements should, in general, meet the transmission performance of any other type of circuit employed except where there are extenuating circumstances.

Most radio systems are operated on a multichannel basis, and it is, of course, important that the system be so designed that it will accept speech from the several channels concerned without overloading the radio terminal equipment. It is important, also, that any signaling tones employed do not interfere with other signaling or other speech

Statistics on Some Typical Carrier Systems, United States

Maker	Code	No. of channels	Frequency range, kc	Channel arrangement	Conductors	Repeater spacing, miles	Automatic regulation	Compandor	Signaling	Remarks

channels. If the radio link has repeaters through which several channels pass in common, they must have a sufficiently high degree of linearity.

A substantial number of intercity trunks are provided by microwave-radio systems which are used alternatively or over the same broad-band channel for television. The telephone circuits are operated on a constant-net-loss basis and, in all operational aspects, are indistinguishable from wire circuits which may form part of the same general network.

An exception in operational procedure is the case of the long transoceanic high-frequency radio links. Because of the variable attenuation and the frequent high-noise characteristics of these paths, the circuit is not set up on a constant-net-loss basis. In addition to the automatic volume control, which normally is part of the radio receiver, it has included in it automatic-gain-control devices, so-called VOGADS (voice-operated gain-adjusting device), which control the gain of the transmitting circuit in accordance with the input speech and ensure loading up the transmitting amplifier to essentially full output capacity at all times, thus providing a maximum signal-to-noise ratio. At the same time, this device reduces the gain in the receiving circuit at times of high gain in the transmitter so that the loop circuits from end to end will not sing.

Radio links employed for mobile service to automobiles or ships pose unusually severe transmission problems that call for automatic gain control somewhat similar to the VOGAD at both terminals. In addition, it is often necessary to employ essentially the same frequencies for opposite directions, and this commonly calls for push-button one-way-at-a-time operation. This is difficult, if not impractical, to tie into a large telephone network otherwise operated on a regular two-way basis.

Since most of the essentially radio problems have been considered in some detail elsewhere in this handbook, this radio section is limited in scope to the few comments noted above.

SPECIAL TRANSMISSION CIRCUITS

A telephone system is frequently called on to provide special circuits for different purposes, not necessarily telephony as such. These include simple telegraph transmission, various types of data-transmission systems, program circuits for radiobroadcasting, and broad-band circuits for television-transmission purposes. It seems likely that, in the course of time, more different types of special circuits will be required.

It serves a useful purpose if such special circuit requirements can be satisfied merely by using a normal telephone channel either directly or with minor modification. This is possible if the special uses have requirements, in respect to band width, phase or delay, band-width–energy distribution, and interference-producing or interference-susceptibility characteristics, which do not differ from regular telephone-circuit characteristics. However, this is frequently not the case and the situation requires special treatment, which may call for the design of new equipment or systems to carry out these functions.

For example, for regular radio-program distribution, band widths of at least 5,000, and sometimes up to 8,000 cps or more, are required. When provided over wire circuits, this may call for specially equalized wider-band one-way wire channels with wide-band loading. More frequently, however, it requires the provision for some wider-band channels in the frequency division of the carrier systems which form a large proportion of the longer-haul circuits in the United States. For example, the frequency range otherwise allotted to two or three regular telephone channels may be employed to provide a wider-band channel of 5 to 8 kc or more in width. These arrangements are embodied in special terminal equipment which supplements some of the terminal equipment employed in the carrier systems. It does not, however, in general, call for a major design of the system.

It has long been common practice to use the voice band of an ordinary telephone channel for the transmission of 12 or more carrier telegraph channels. Other forms of data-transmission systems, as well as picture-transmission systems, have been commonly applied to telephone channels. In the latter case particularly, it is necessary

practice to delay-equalize the circuits involved specially because of the sensitivity of the system to this particular kind of distortion.

The transmission of television signals is, of course, a very unique case since it calls for a width of frequency band and precision of amplitude and delay equalization far beyond any ordinary speech channel. Its requirements can be met by the use of special video pairs, as noted under Wire Circuits, for short distances and by coaxial systems, such as the Western Electric Company L3 system and various types of microwave-radio systems.
